Enteric Gram-Negative Rods (Enterobacteriaceae)

INTRODUCTION

The Enterobacteriaceae are a largest, most heterogeneous collection of medically important gram-negative rods, 48 genera, whose natural habitat is the intestinal tract of humans and animals.

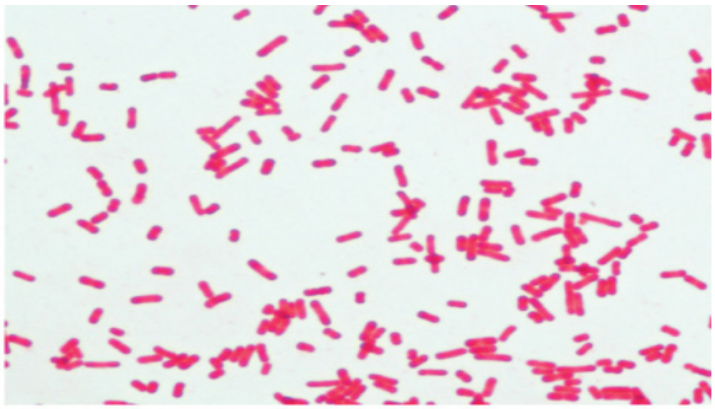
The family includes many genera (*Escherichia, Shigella, Salmonella, Enterobacter, Klebsiella, Serratia, Proteus,* and others).

- *Escherichia coli,* are part of the normal flora and incidentally cause disease

- Salmonellae and shigellae, are regularly pathogenic for humans.

The Enterobacteriaceae are facultative anaerobes or aerobes, ferment a wide range of carbohydrates, possess a **complex antigenic structure**, and produce a variety of toxins and other virulence factors. Enterobacteriaceae, enteric gram-negative rods (enteric bacteria), or (coliforms).

The Enterobacteriaceae are short gram-negative rods (Figure1). Typical morphology is seen in growth on solid media in vitro, but morphology is highly variable in clinical specimens. Capsules are large and regular in *Klebsiella*, less so in *Enterobacter*, and uncommon in the other species.



Human pathogen :

Enterobacteriaceae as a group were originally divided into pathogens and non-pathogens based on their ability to cause diarrheal disease of humans.

The pathogenic most important genera were *Salmonella* and *Shigella.* However, it is now known that *E. coli* causes at least five types of gastrointestinal disease in humans.

1.Escherichia coli:

Most *E. coli* strains are harmless, there are others that cause disease in humans and animals that have evolved to become important pathogens in their own right. Clinically, two distinct types of pathogenic *E. coli* are recognized.

I- Extra-intestinal pathogenic *E. coli* (ExPEC) includes those *E. coli* associated with newborn meningitis (NBM) or sepsis and urinary tract infections (UTIs).

II- Intestinal pathogenic *E. coli* (IPEC) includes *E. coli* responsible for a range of distinct classes of diarrhoeal disease.

Pink (lactose positive) colony with surrounding pink area on MacConkey*, Ferments glucose,* lactose, trehalose, & xylose, Positive indole and methyl red tests, Does NOT produce H2S or phenylalanine deaminase, Simmons citrate negative, Usually motile, Voges-Proskauer test negative.

Infections Caused by Pathogenic *E. coli*

E. coli is responsible primarily for three types of infections in humans: urinary tract infections, neonatal meningitis, and intestinal diseases.

The strains that associated with gastrointestinal disease are classified as follow:

A- Enteroinvasive E. coli (EIEC) :

Strains belonging to this group are biochemically, genetically and pathogenically closely related to *Shigella* spp. The most common symptom is watery diarrhoea which may precede dysenteric stools containing mucus and blood. In severe cases the bacteria may attack the colonic mucosa, invading epithelial cells, multiplying and causing ulceration of the bowel.

B- Enterotoxigenic *E. coli* (ETEC) :

Strains belonging to the ETEC pathotype are characterized by the production of at least one of two types of enterotoxin: LT (heat-labile enterotoxin) and ST (heat-stable enterotoxin). Cause “traveler’s diarrhea”; watery diarrhea without blood; self-limiting; usually not identified**.**

C-Enteroaggregative *E. coli* (EAEC*) :*

Cause diarrhea by adhering to the mucosal surface of the intestine; watery diarrhea; symptoms may persist for over two weeks, EAggEC (or EAEC) are a major cause of chronic infantile diarrhoea and they have also emerged as a cause of diarrhoeal disease in adults and children in developed countries. Toxins that have also been associated with

strains of EAggEC include an *E. coli* heat-stable-like enterotoxin termed enteroaggregative heat-stable toxin-1 (EAST-1) and a heat-labile toxin.

D-Enteropathogenic *E. coli* (EPEC) :

Primarily in infants and children; outbreaks in hospital, nurseries, and day care centers; stool has mucous but not blood; identified by serotyping.

E-Enterohaemorrhagic *E. coli* (EHEC) :

(EHEC serotype 0157:H7) – associated with hemorrhagic diarrhea and hemolytic-uremic syndrome (HUS), which includes low platelet count, hemolytic anemia, and kidney failure; potentially fatal, especially in young children; does NOT ferment sucrose; identified by serotyping. EHECs have emerged as one of the most important threats to human health.

Klebsiella:

It is gram negative , non-motile, capsulate, thick& bacilli producing mucoid pink colonies on MacConky medium, it is found in mucosa of upper respiratory tract, intestinal & urinary tract, it is member of Normal flora that may cause sever systemic infection under certain condition such as immunocompromise debilitation.

Klebsiella pneumoniae

Is the causative agent of pneumonia & lung abscesses also may cause urinary tract infections.

Virulence factor for *Klebsiella pneumoniae*

1-capsular mucoid polysaccharide which can resist to action of phagocytes.
2-some strain carry plasmid coding for production heat –stable enterotoxine
3-they contain resistance plasmids (R-plasmids) which gives resistance to antibiotic

2. Proteus:

Proteus species move very actively by means of peritrichous flagella, resulting in "swarming" on solid media unless the swarming is inhibited by chemicals, eg, phenylethyl alcohol or CLED (cystine-lactose-electrolyte-deficient) medium. Strains of Proteus vary greatly in antibiotic sensitivity. *P mirabilis* is often inhibited by penicillins; the most active antibiotics for other members of the group are aminoglycosides and cephalosporins. *Proteus* species are urease-positive, ferments lactose very slowly or not at all.

Pathogenecity: it is opportunistic pathogen cause urinary tract infection ,may produce Pyogenic lesion like abscess infection of wound ,ear or respiratory tract.

4. *Shigella*—Shigellae are nonmotile and usually do not ferment lactose but do ferment other carbohydrates like glucose, producing acid but not gas. They do not produce H_2S (in triple sugar iron test). The four *Shigella* species are closely related to *E coli.*

5. *Salmonella*—Salmonellae are motile rods that characteristically ferment glucose and mannose without producing gas but do not ferment lactose or sucrose. Most salmonellae produce H_2S. They are often pathogenic for humans or animals when ingested.

The **Triple Sugar Iron** (**TSI**) test is a microbiological test roughly named for its ability to test a microorganism's ability to ferment **sugars** and to produce hydrogen sulfide. It is often used in the selective identification of enteric bacteria including Salmonella and **Shigella**.

Antigenic Structure :

Enterobacteriaceae have a complex antigenic structure. They are classified by:

-More than 150 different heat-stable somatic O (lipopolysaccharide) antigens.

- More than 100 heat-labile K (capsular) antigens. In *Salmonella typhi,* the capsular antigens are called Vi antigens.

- More than 50 H (flagellar) antigens .

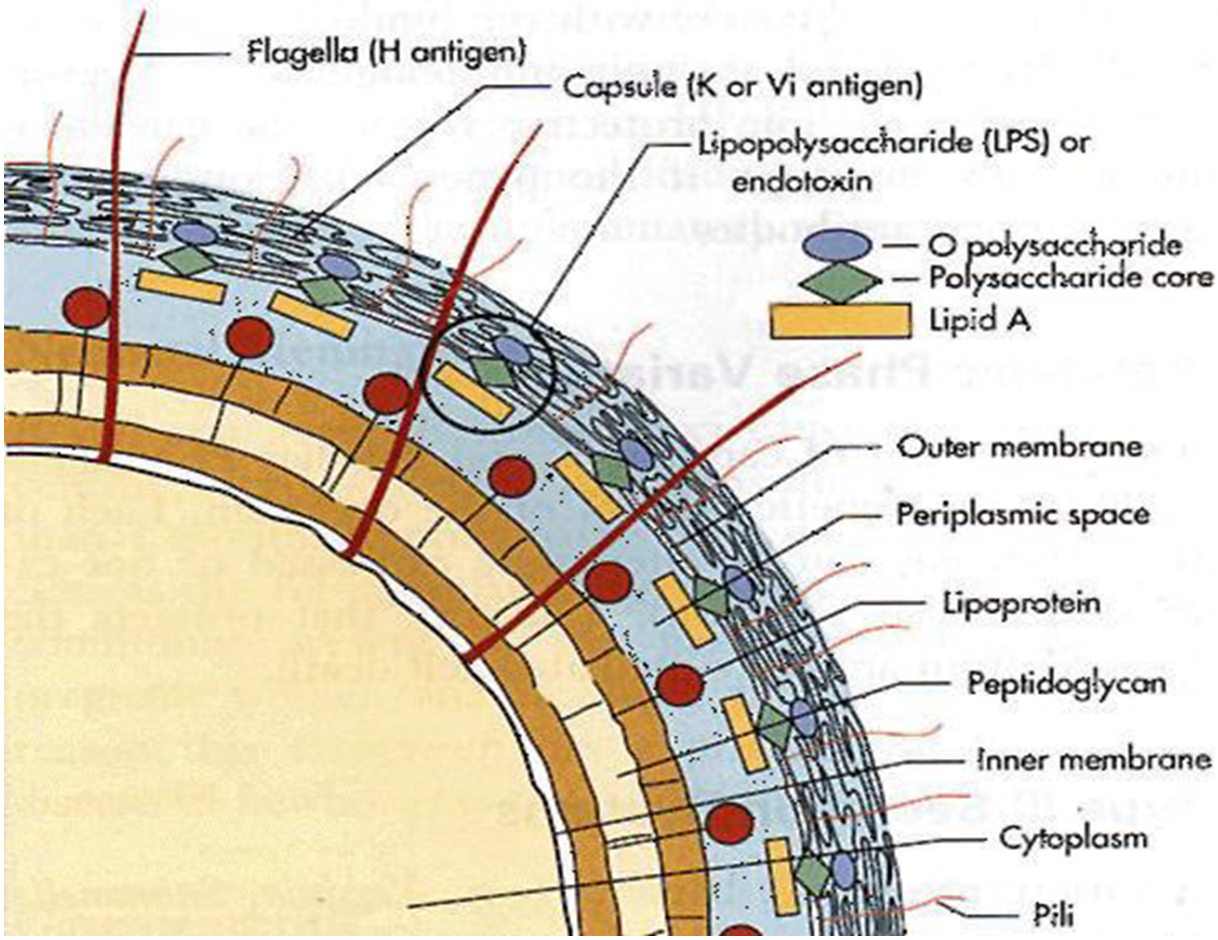


Figure : Antigenic structure of Enterobacteriaceae.

Colicins (Bacteriocins)

Many gram-negative organisms produce bacteriocins. These high-molecular-weight bactericidal proteins are produced by certain strains of bacteria active against some other strains of the same or closely related species. Their production is controlled by plasmids. Colicins are produced by *E coli*. Bacteriocin-producing strains are resistant to their own bacteriocin; thus, bacteriocins can be used for "typing" of organisms.

Toxins & Enzymes

Most gram-negative bacteria possess complex lipopolysaccharides in their cell walls. These substances, cell envelope (cytoplasmic membrane, peptidoglycan, outer membrane) endotoxins.

Many gram-negative enteric bacteria also produce exotoxins of clinical importance.

Shigella :The natural habitat of shigella is limited to the intestinal tracts of humans and other primates, where they produce bacillary dysentery.

Morphology & Identification

Shigella are slender gram-negative rods; coccobacillary forms occur in young cultures.

CULTURE :

Shigella are facultative anaerobes but grow best aerobically. Convex, circular, transparent colonies with intact edges reach a diameter of about 2 mm in 24 hours.

GROWTH CHARACTERISTICS :

All shigella ferment glucose. They do not ferment lactose. Shigellae form acid from carbohydrates but rarely produce gas. They may also be divided into those that ferment mannitol and those that do not .

Pathogenesis & Pathology

Shigella infections are almost always limited to the gastrointestinal tract; bloodstream invasion is quite rare. Shigella are highly communicable; the infective dose is on the order of 10^3 organisms (whereas it usually is 10^5–10^8 for salmonellae and vibrios).

The essential pathologic process is :-

-Invasion of the mucosal epithelial cells (e.g., M cells) by induced phagocytosis

-Escape from the phagocytic vacuole.

-Multiplication and spread within the epithelial cell cytoplasm, and passage to adjacent cells.

Micro abscesses in the wall of the large intestine and terminal ileum lead to necrosis of the mucous membrane, superficial ulceration, bleeding, and formation of a "pseudomembrane" on the ulcerated area. This consists of fibrin, leukocytes, cell debris, a necrotic mucous membrane, and bacteria. As the process subsides, granulation tissue fills the ulcers and scar tissue forms.

Toxins

Endotoxin :

All shigellae release their toxic lipopolysaccharide. This endotoxin probably contributes to the irritation of the bowel wall.

***Shigella dysenteriae* exotoxin :**

S. dysenteriae type 1 (Shiga bacillus) produces a heat-labile exotoxin that affects both the gut and the central nervous system. The exotoxin is:

- protein that is antigenic (stimulating production of antitoxin)
- lethal for experimental animals.
- Acting as an enterotoxin, it produces diarrhea as does the *E coli* Shiga-like toxin
- inhibits sugar and amino acid absorption in the small intestine.
-Acting as a "neurotoxin," this material may contribute to the extreme severity and fatal nature of *S dysenteriae* infections.

Diagnostic Laboratory Tests

Specimens :

Specimens include fresh stool, and rectal swabs for culture. Large numbers of fecal leukocytes and some red blood cells often are seen microscopically.

Culture :

The materials are streaked on differential media (eg, MacConkey or EMB agar) and on selective media (Hektoen enteric agar or *Salmonella-Shigella* agar), which suppress other Enterobacteriaceae and gram-positive organisms. Colorless (lactose-negative) colonies are inoculated into triple sugar iron agar. Organisms that fail to produce H_2S, that produce acid but not gas in triple sugar iron agar medium, and that are nonmotile should be subjected to slide agglutination by specific *Shigella* antisera.

Treatment :

Ciprofloxacin, ampicillin, doxycycline, and trimethoprim-sulfamethoxazole are most commonly inhibitory for *Shigella* isolates and can suppress acute clinical attacks of dysentery and shorten the duration of symptoms.

***Salmonella** :*

Salmonella are often pathogenic for humans or animals when acquired by the oral route. They are transmitted from animals and animal products to humans, where they cause enteritis, systemic infection, and enteric fever.

Morphology & Identification :

Salmonella vary in length. Most isolates are motile with peritrichous flagella. Salmonellae grow readily on simple media, but they almost never ferment lactose or sucrose. They usually produce H_2S. They survive freezing in water for long periods. Salmonellae are resistant to certain chemicals (eg, brilliant green, sodium tetrathionate, sodium deoxycholate) .

Pathogenesis & Clinical Findings :

Salmonella typhi, *Salmonella choleraesuis*, *Salmonella paratyphi* A and *Salmonella paratyphi* B are primarily infective for humans. The vast majority of salmonellae, however, are chiefly pathogenic in animals that constitute the reservoir for human infection: poultry, pigs, rodents, cattle, pets (from turtles to parrots), and many others.

The organisms almost always enter via the oral route, usually with contaminated food or drink. The infective dose to produce clinical or subclinical infection in humans is 10^5–10^8 salmonellae (but perhaps as few as 10^3*Salmonella* Typhi organisms). Among the host factors that contribute to resistance to salmonella infection are gastric acidity, normal intestinal microbial flora, and local intestinal immunity.

Salmonellae produce three main types of disease in humans, but mixed forms are frequent

1- THE "ENTERIC FEVERS" (TYPHOID FEVER)

This syndrome is produced by only a few of the salmonellae, of which *Salmonella* Typhi (typhoid fever) is the most important. The ingested salmonellae reach the small intestine, from which they enter the lymphatics and then the bloodstream. They are carried by the blood to many organs, including the intestine. The organisms multiply in intestinal lymphoid tissue and are excreted in stools.

After an incubation period of 10–14 days, fever, malaise, headache, constipation, bradycardia, and myalgia occur. The fever rises to a high plateau, and the spleen and liver become enlarged. Rose spots, usually on the skin of the abdomen or chest, are seen briefly in rare cases. The white blood cell count is normal or low. the mortality rate was 10–15%. Treatment with antibiotics has reduced the mortality rate to less than 1%.

2- bacteremia with focal lesions

This is associated commonly with *S choleraesuis* but may be caused by any salmonella serotype. Following oral infection, there is early invasion of the bloodstream (with possible focal lesions in lungs, bones, meninges, etc), but intestinal manifestations are often absent. Blood cultures are positive.

3- enterocolitis

This is the most common manifestation of salmonella infection. Eight to 48 hours after ingestion of salmonellae, there is nausea, headache, vomiting, and profuse diarrhea, with few leukocytes in the stools. Low-grade fever is common, but the episode usually resolves in 2–3 days. Inflammatory lesions of the small and large intestine are present. Bacteremia is rare (2–4%) except in immunodeficient persons. Blood cultures are usually negative, but stool cultures are positive for salmonellae and may remain positive for several weeks after clinical recovery.

Diagnostic Laboratory Tests

Specimens

Blood for culture must be taken repeatedly. In enteric fevers and septicemias, blood cultures are often positive in the first week of the disease. Bone marrow cultures may be useful. Urine cultures may be positive after the second week.

Stool specimens also must be taken repeatedly. In enteric fevers, the stools yield positive results from the second or third week on; in enterocolitis, during the first week.

Bacteriologic methods for isolation of salmonellae

1. Differential medium cultures—EMB, MacConkey, or deoxycholate medium permits rapid detection of lactose non-fermenters (not only salmonellae and shigellae but also *Proteus*, *Serratia*, etc). Bismuth sulfite medium permits rapid detection of salmonellae which form black colonies because of H_2S production. Many salmonellae produce H_2S.

2. Selective medium cultures—The specimen is plated on salmonella-shigella (SS) agar, Hektoen enteric agar, or deoxycholate-citrate agar, which favor growth of salmonellae and shigellae over other Enterobacteriaceae.

3. Enrichment cultures—The specimen (usually stool) also is put into selenite F or tetrathionate broth, both of which inhibit replication of normal intestinal bacteria and permit multiplication of salmonellae. After incubation for 1–2 days, this is plated on differential and selective media.

4. Final identification—Suspect colonies from solid media are identified by biochemical reaction patterns and slide agglutination tests with specific sera.

SEROLOGIC METHODS

1. Agglutination test—In this test, known sera and unknown culture are mixed on a slide. Clumping, when it occurs, can be observed within a few minutes. This test is particularly useful for rapid preliminary identification of cultures. There are commercial kits available to agglutinate and serogroup salmonellae by their O antigens: A, B, C_1, C_2, D, and E.

2. Tube dilution agglutination test (Widal test)—Serum agglutinins rise sharply during the second and third weeks of *Salmonella* Typhi infection. The Widal test to detect these antibodies against the O and H antigens has been in use for decades. At least two serum specimens, obtained at intervals of 7–10 days, are needed to prove a rise in antibody titer. Serial dilutions of unknown sera are tested against antigens from representative salmonellae. False-positive and false-negative results occur.

Treatment :

While enteric fevers and bacteraemia with focal lesions **require antimicrobial treatment**, the vast majority of cases of enterocolitis do not. Antimicrobial treatment of *Salmonella* enteritis in neonates is important. In enterocolitis, clinical symptoms and excretion of the salmonellae may be prolonged by antimicrobial therapy. In severe diarrhea, replacement of fluids and electrolytes is essential.

Antimicrobial therapy of invasive *Salmonella* infections is with ampicillin, trimethoprim-sulfamethoxazole, or a third-generation cephalosporin. Multiple drug resistance transmitted genetically by plasmids among enteric bacteria is a problem in *Salmonella* infections. Susceptibility testing is an important adjunct to selecting a proper antibiotic.

CARRIERS :

After manifest or subclinical infection, some individuals continue to harbor salmonellae in their tissues for variable lengths of time (convalescent carriers or healthy permanent carriers). Three percent of survivors of typhoid become permanent carriers, harboring the organisms in the gallbladder, biliary tract, or, rarely, the intestine or urinary tract.

Sources of infection :

The sources of infection are food and drink that have been contaminated with salmonellae. The following sources are important:

1. Water—Contaminated with feces often results in explosive epidemics.

2. Milk and other dairy products (ice cream, cheese, custard)—Contaminated with feces and inadequate pasteurization or improper handling.

3. Shellfish—From contaminated water.

4. Dried or frozen eggs—From infected fowl or contaminated during processing.

5. Meats and meat products—From infected animals (poultry) or contamination with feces by rodents or human

Prevention & Control

1-prevent contamination of food and water by rodents or other animals that excrete salmonellae.

2-Infected poultry, meats, and eggs must be thoroughly cooked.

3-Carriers must not be allowed to work as food handlers and should observe strict hygienic precautions.

4-Two typhoid vaccines are currently available: an oral live, attenuated vaccine and a Vi capsular polysaccharide vaccine for intramuscular use.

5-Vaccination is recommended for travelers to endemic regions especially if the traveler visits rural areas or small villages where food choices are limited.

Fusiform and Spirochaetes

Zainab kamil yousif

Medical microbiology

Third year

Fusobacterium

- *Fusobacterium* is a genus of anaerobic, Gram-negative, non-sporeforming bacteria, similar to *Bacteroides*. Individual cells are slender, rod-shaped bacilli with pointed ends.[2][3] Strains of *Fusobacterium* cause several human diseases, including periodontal diseases and topical skin ulcers.

Fusobacterium

- *Fusobacterium* spp. can be somewhat variable in their Gram stain and display a range of cellular morphologies from coccoid, pleomorphic spherules *(Fusobacterium necrophorum)* to rod shaped. Rods can be short with rounded ends or long and thin with pointed ends *(F. nucleatum)*, arrayed end to end

- Although older sources state that *Fusobacterium* is part of the normal flora of the human oropharynx, the current consensus is that *Fusobacterium* should always be treated as a pathogen.

Fusobacterium necrophorum

- Gram negative, non spore forming anaerobe, fusiform or pointed rod bacteria. Its normal inhabitant is the alimentary tract of animals and humans, the source of infection is always endogenous.
- Virulent spp. Include Fusobacterium necrophorum, Fusobacterium equinum, and Fusobacterium nucleatu

They differ morphologically and biologically. The organism is an opportunistic pathogen that causes numerous necrotic conditions called (necrobacillosis) such as bovine hepatic abscesses, ruminant foot abscesses and human oral infections.

Pathogenesis

- The pathogenic mechanism of necrophorum is complex and not well defined. Several toxins, such as leukotoxin, endotoxin, haemolysin, haemagglutinin and adhesin, have been implicated as virulence factors. Among these, leukotoxin and endotoxin are believed to be more important than other toxins in overcoming the host's defence mechanisms to establish the infection.

Diseases •

- Foot abscesses in Cattle and Sheep infection of the interdigital and adjacent soft tissues and is the major cause of lameness in beef and dairy cattle. Foot rot in sheep is a mixed bacterial infection of the interdigital skin.

Thrush (hoof infection) horses caused by F. necrophorum.

- Bovine mastitis (summer mastitis) caused by F necrophorum alone has been reported F. necrophorum is the primary aetiological agent of bovine hepatic abscesses, from which it is frequently isolated in pure culture.
-

Diagnosis

- Gram stain reveals long gram negative fusiform rods with characteristic beading.
- Colonies are small, smooth, yellowish white, and may be α or β hemolytic.

- **Treatment :**
- Erythromycin , Tetracycline and penicillin for prevention of bovine foot rot in sheep
-

Antibiotic sensitivity and biochemical test

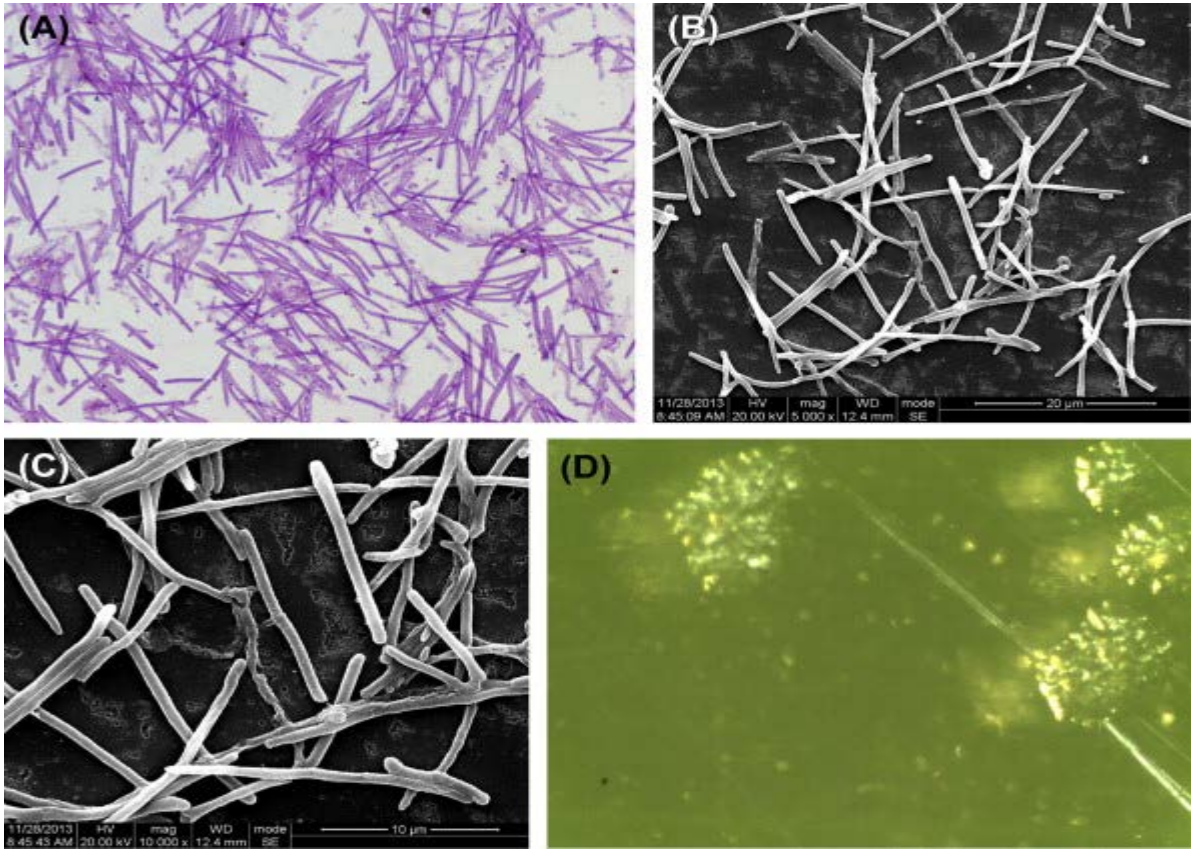
- As a genus, *Fusobacterium* is sensitive to both kanamycin and colistin and resistant to vancomycin. It can be distinguished by its bile sensitivity. Most species are indole positive and produce butyric acid during the fermentation of glucose.

Leptotrichia

Leptotrichia species are typically large, fusiform-shaped, non-sporulating, and non-motile rods, facultative anaerobic / anaerobic bacteria that are found mostly in the oral cavity and some other parts of the human body, in animals, and even in ocean sediments. All species ferment carbohydrates and produce lactic acid that may be involved with tooth decay.

-

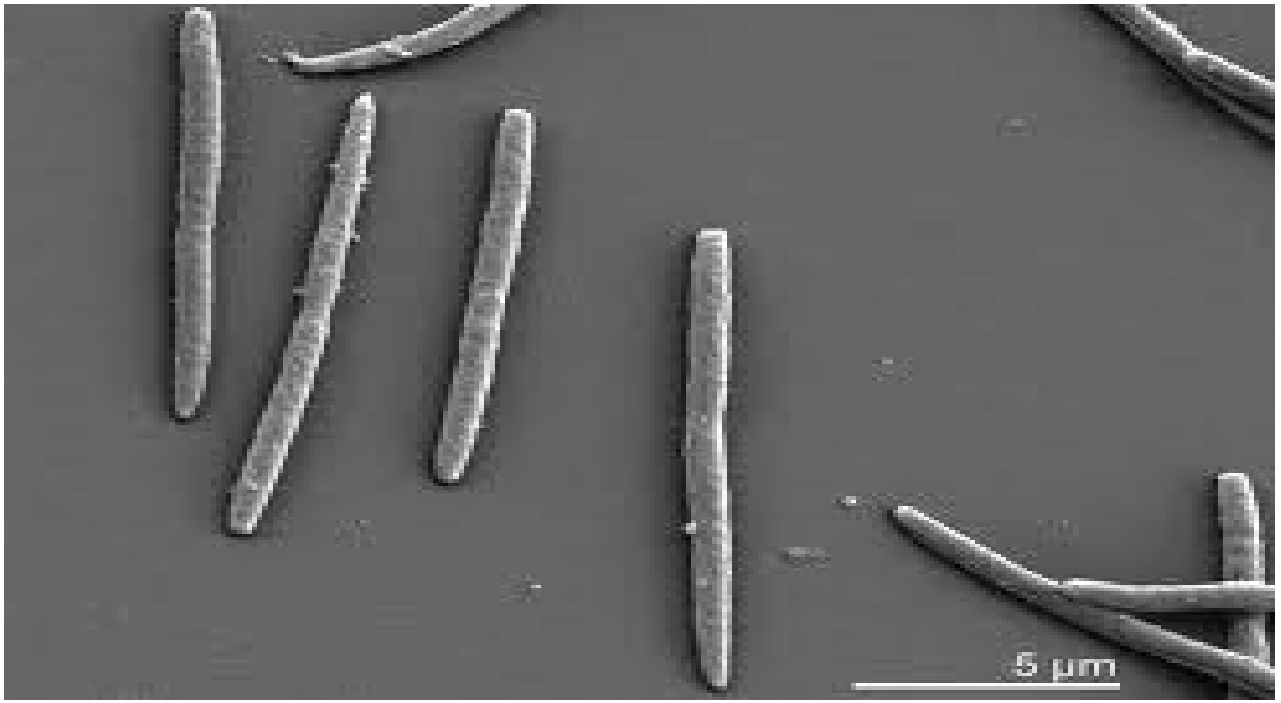
Leptotrichia Spp. (A) *Leptotrichia* cells (Gram stain). (B) *Leptotrichia* cells (SEM). (C) *Leptotrichia* cells (SEM). (D) *Leptotrichia* colonies.



Leptotrichia buccalis

- ***Leptotrichia buccalis*** is an anaerobic, Gram-negative rod bacteria. It is a constituent of normal oral flora.
- *Leptotrichia buccalis* can be clearly identified using live blood analysis in dark field. They have a distinct form, which separates them from other rod forms.

Leptotrichia buccalis



Pathology

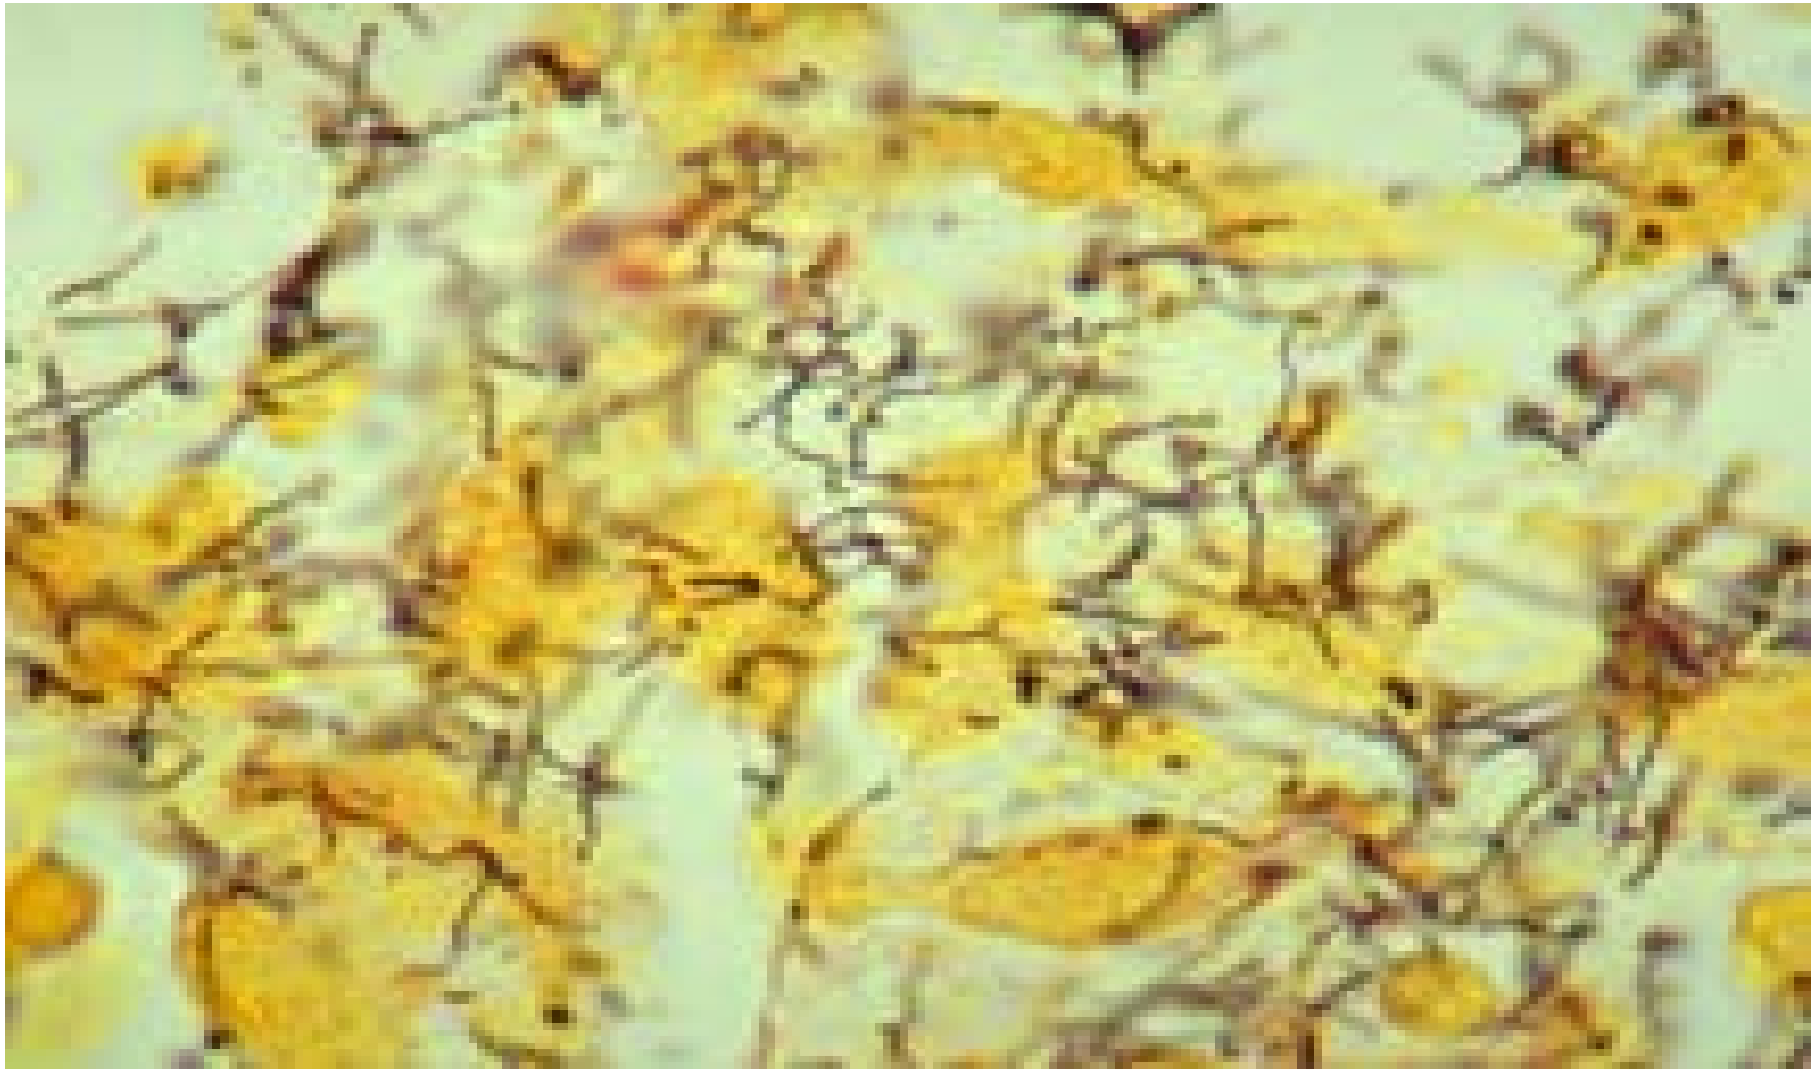
- Almost every case of severe infection with *Leptotrichia buccalis* reported in medical literature occurred in patients with neutropenia, Holistic dentists claim that dental granulomas following root canal fillings are likely to be caused by *Leptotrichia buccalis*. The majority of patients with '*Leptotrichia buccalis* found in their blood have had root canal fillings, which would support the claim of holistic dentists.

- Thirty-one cases of bacteremia and four cases of wound infections associated with *Leptotrichia* species. Bacteremia caused by *Leptotrichia* species were found among neutropenic patients with various forms of predisposing diseases such as bone-marrow transplants, infective endocarditis, and sepsis associated with mucositis.

Identification of *Leptotrichia* species

- Identification of *Leptotrichia* species can be problematic in terms of culturing because some strains are strictly anaerobic or facultative anaerobic, while others prefer growth under the influence of CO_2. *Leptotrichia* species usually stain Gram-negative, but fresh cells may be Gram-positive.

- It can ferment fructose, glucose, maltose, mannose, sucrose, and trehalose to produce acid. Do not produce indole, catalase, urease, H_2S and phospholipase.



Spirochaetes

Spirochaetes

- The spirochetes are a distinct group of bacteria which have :
- a unique cell morphology and mode of motility. Spirochetes are simple Gram-negative bacteria, have a characteristic long helical shape.

SPIROCHETES

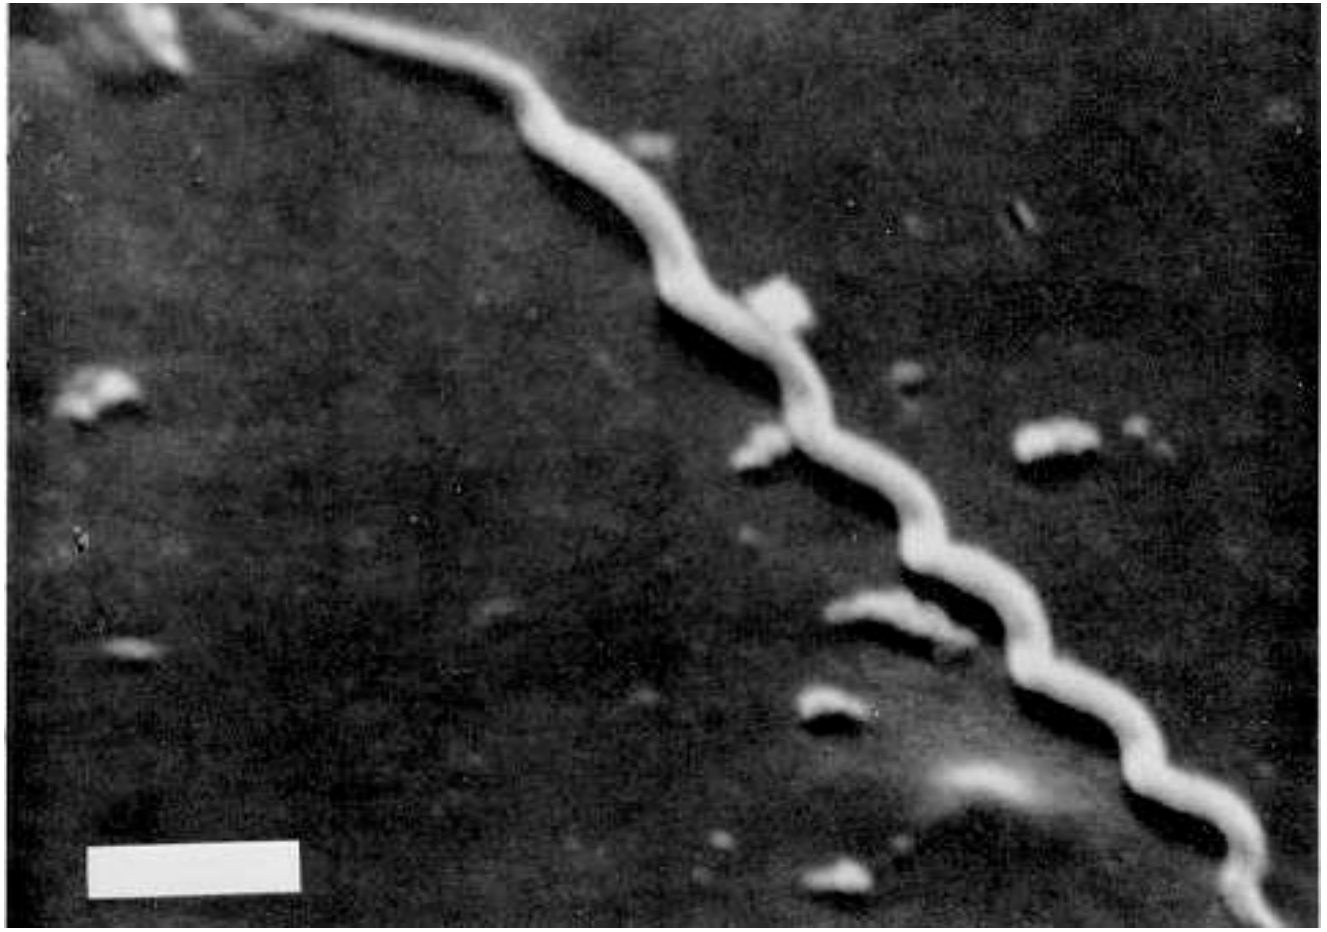
Spirochetes, a group of five genera, very widespread in nature and found in the fresh waters, of which are pathogenic for humans:

- ***Treponema***
- ***Borrelia***
- ***Leptospira***

Disease-causing members of these Genera

- *Treponema pallidum*, which causes syphilis
- *Leptospira* species, which causes leptospirosis
- *Borrelia recurrentis*, which causes relapsing fever

Treponema pallidum **(Nichols strain) attached to cultured mammalian cells**.

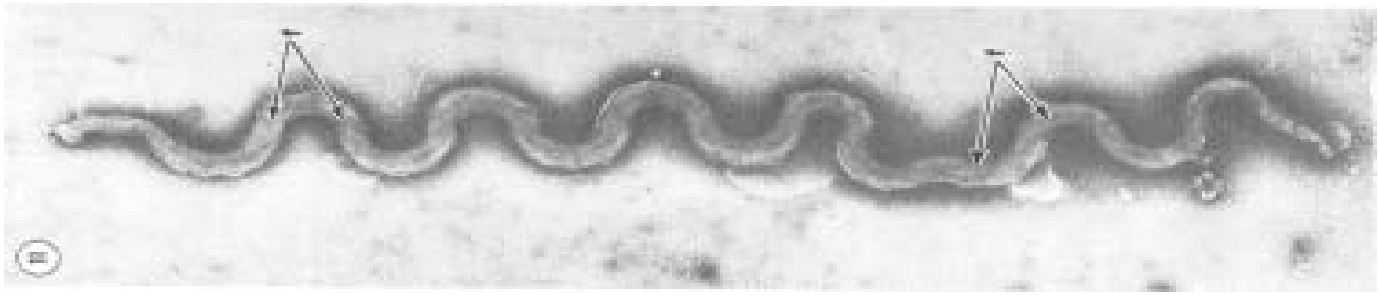


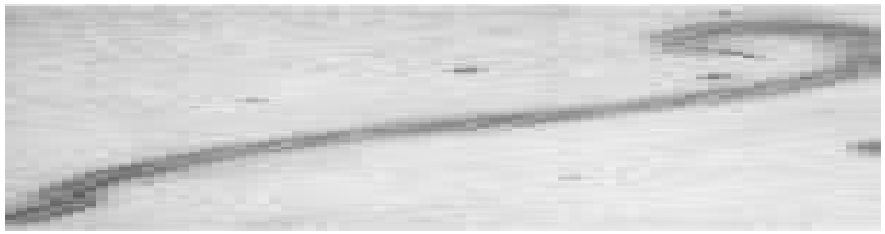
- Some are tightly coiled like a telephone cord, while others are more open;

  Very tight coils are seen in Leptospira,

  Medium coils in Treponema and

  Open coils are seen in Borrelia.



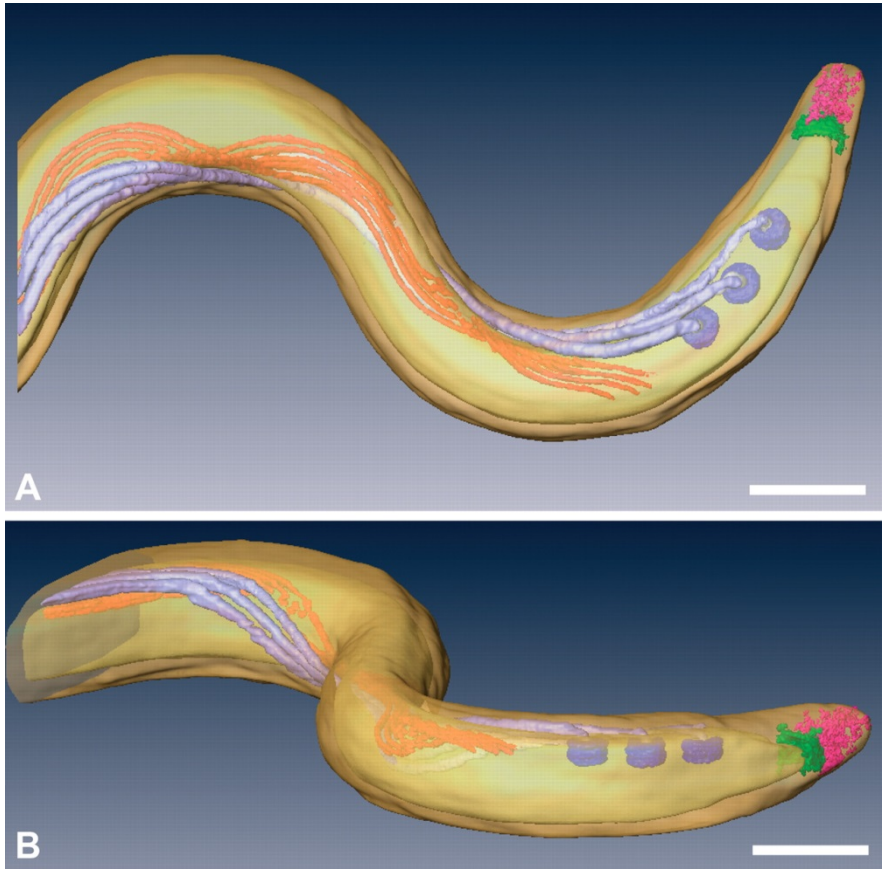


- ***Treponema pallidum***
- Exhibits characteristic motility that consists of rapid rotation about its longitudinal axis and bending, flexing, and snapping about its full length
- Multiplication is by binary transverse fission.
- Treponemes have not yet been cultured in vitro. *Treponema pallidum* is the causative agent of syphilis, a sexually transmitted disease (STD).

TREPONEMES

CELL WALL STRUCTURE

- The organism has an outer membrane containing an extremely low density of surface-exposed transmembrane proteins.
- Typically, three flagella originate from each end of the bacterium, and, winding about the bacterium within the periplasmic space, overlap at the midpoint.



Treponema

- **Virulence Factors**
- Several gene products associated with virulent strains,
  - Their roles in pathogenesis are unknown.
- The outer membrane proteins are associated with adherence to the surface of host cells,
- Virulent spirochetes produce hyaluronidase, which may facilitate perivascular infiltration.
- Virulent spirochetes are also coated with host cell fibronectin, which can protect against phagocytosis.

PATHOGENESIS

- Treponemes are highly invasive pathogens which often disseminate relatively soon after inoculation.

- Evasion of host immune responses appears to be, at least in part, due to the unique structure of the treponemal outer membrane (i.e., its extremely low content of surface-exposed proteins).

- Although treponemes lack classical lipopolysaccharide (endotoxin), they possess abundant lipoproteins which induce inflammatory processes.

Transmission of Syphilis

A. Syphilis is spread mostly by sexual contact.

B. except for congenital syphilis, which is spread from mother to fetus transplacentally or by passage through an infected birth canal.

C. Transmission by transfusion has been documented.

Chain of infection

Transmission by sexual contact requires:

1-exposure to moist lesions of skin or mucous membranes.

2- Depends on the existence of infectious lesions (sores), which may or may not be visible.

3- To disseminate away from the site of initial entry, organisms must traverse the viscous ground substance between tissue cells.

Treatment

- Syphilis is relatively easily treated with antibiotics such as penicillin, usually given as consecutive daily intramuscular injections. Patients who are allergic to penicillin may be treated with tetracycline.
- Fortunately, unlike other STDs such as gonorrhea, there is little evidence of antibiotic resistance developing in syphilis.

Thank you

Microbiology / Third class 10th lecture /2/2021

Lactobacilli, Corynebacteria and Propionibacteria

Lactobacilli

Lactobacilli are saprophytes in vegetable and animal material (e.g. milk). Some species are common animal and human commensals inhabiting the oral cavity and other parts of the body. They have the ability to tolerate acidic environments and hence are believed to be associated with the carious process.

The taxonomy of lactobacilli is complex. They are characterized into two main groups: -

-**Homofermenters**, which produce mainly lactic acid (65%) from glucose fermentation (e.g. *Lactobacillus casei*),

- **Heterofermenters**, which produce lactic acid as well as acetate, ethanol and carbon dioxide (e.g. *Lactobacillus fermentum*). *L. casei* and *Lactobacillus rhamnosus*, *Lactobacillus acidophilus* and the newly described species, *Lactobacillus oris*, are common in the oral cavity. It should be noted that the taxonomy of lactobacilli is under constant revision**.**

Habitat and transmission

Lactobacilli are found in the oral cavity, gastrointestinal tract and female genital tract. In the oral cavity, they constitute less than 1% of the total flora. Transmission routes are unknown**.**

Characteristics

Gram-positive coccobacillary forms (mostly bacillary), α- or non-haemolytic, facultative anaerobes. These organisms ferment carbohydrates to form acids (i.e. they are acidogenic) and can survive well in acidic milieu (they are aciduric);they may be homofermentative or heterofermentative. The question as to whether they are present in carious lesions because they prefer the acidic environment, or whether they generate an acidic milieu and destroy the tooth enamel, has been debated for years.

Lactobacilli are also major constituents of the vaginal flora and help maintain its low pH equilibrium. Recently, the beneficial role of lactobacilli in maintaining the homoeostasis of the intestinal flora has been recognized, and lactobacillus-laced' food items have gained popularity among the health-conscious public**.**

Culture and identification

Lactobacilli grow under microaerophilic condition in the presents of carbon dioxide and at acidic pH(6) media enriched with glucose or blood promote growth. A special selective

medium, tomato juice agar (pH 5.0), promotes the growth of lactobacilli while suppressing other bacteria. Identification is by biochemical reactions**.**

Pathogenicity

Lactobacilli are frequently isolated from deep carious lesions where the pH tends to be acidic. Indeed, early workers believed that lactobacilli were the main cariogenic agent (a theory that has been disproved), so much so that the number of lactobacilli in saliva (the lactobacillus count) was taken as an indication of an individual's caries activity. Although this test is not very reliable, it is useful for monitoring the dietary profile of a patient because the level of lactobacilli correlates well with the intake of dietary carbohydrate.

Endocarditis

Among infections caused by lactobacilli, endocarditis, with or without bacteremia, is the most common. It occurred in patients who had dental extractions or gingival bleeding after tooth brushing , suggesting that these could be considered risk factors, especially in the presence of underlying immunosuppression and valvular heart disease

Lactobacillus organisms are rarely associated with pathology in immunocompetent people, but in the presence of risk factors and underlying conditions, they can cause infections such as endocarditis, bacteremia, neonatal meningitis, dental caries, and intra-abdominal abscesses including liver abscess, pancreatic necrosis infection, pulmonary infections, pyelonephritis, meningitis, postpartum endometritis, and chorioamnionitis

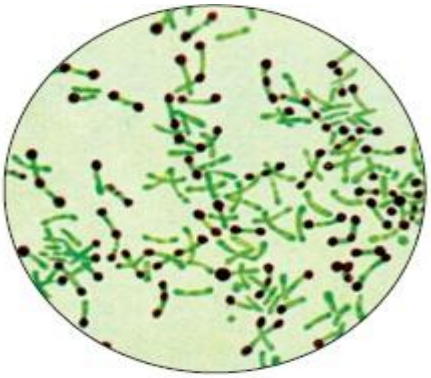
Corynebacteria

The genus *Corynebacterium* contains many species that are widely distributed in nature. These Gram-positive bacilli demonstrate pleomorphism (i.e. coccobacillary appearance) and are non-sporing, non-capsulate and non-motile. In common with *Mycobacterium* and *Nocardia* spp., they have a cell wall structure containing mycolic acid. A number of species are important human pathogens and commensals. The sometimes fatal upper respiratory tract infection of childhood **diphtheria** is caused by *Corynebacterium diphtheriae*.It is important to distinguish this, and other pathogens within the genus, from commensal Corynebacteria.

Corynebacterium diphtheriae

Habitat and transmission

Human throat and nose, occasionally skin; patients carry toxigenic organisms up to 3 months after infection. Transmission is via respiratory droplets**.**



Albert's Metachromatic Stains Kit
(K002)
Metachromatic Granules - Black
Cytoplasm - Light Green

Characteristics

Pleomorphic, Gram-positive, club-shaped (tapered at one end) bacilli, 2–5 μm in length, arranged in palisades. They divide by 'snapping fission' and hence are arranged at angles to each other, resembling Chinese characters. The rods have a beaded appearance, with the beads comprising an intracellular store of polymerized phosphate. The granules stain metachromatically with special stains such as Albert,s Metachromatic stain (green bacilli with metachromatic granules).

Culture and identification

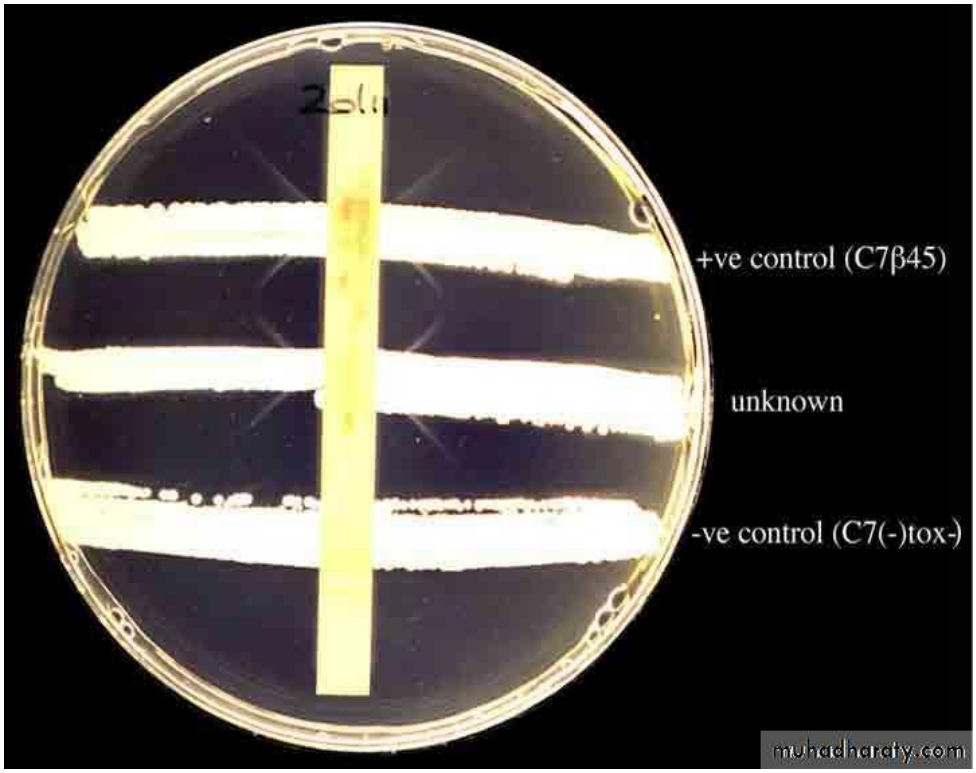
A non-fastidious, facultative anaerobe that grows well at 37° .C. Grows on blood agar but selective media are helpful for isolation from clinical specimens. In blood tellurite agar, commonly used for this purpose, Corynebacteria produced is tinctive grey-black colonies after 48-h incubation at 35° C. Preliminary identification is helped by the shape and size of the colonies on tellurite agar. Specific identification is by biochemical reactions and demonstration of toxin production. The test for toxin production is important as some corynebacteria are non-toxigenic (and hence non-virulent) and are normal skin or throat commensals. C.diphtheriae can be killed at 58 ^{0}C in 10 mint 100 ^{0} C in 1 mint ,survive in blankets, floor dust, toys inanimate objects.

Corynebacterium diphtheriae infects the nasopharynx or skin. Toxigenic strains secrete a potent exotoxin which may cause diphtheria. Nontoxigenic strains of C diphtheriae are rarely .associated with clinical disease

Toxin production

The exotoxin responsible for virulence can be demonstrated by the gel precipitation test, which uses the **Elek plate**. In this test, a filter paper soaked in diphtheria antitoxin is incorporated into serum agar before it has set; the test strain of *C. diphtheriae* under investigation is then streaked on to the agar at right angles to the filter-paper strip and incubated at 37° C. After 24 h, white lines of precipitation will be visible as a result of the combination of the antitoxin and the antigen (i.e. the toxin) if the strain is a toxigenic isolate (Fig. 1). Although this is the traditional method for toxin detection, enzyme-linked immunosorbent assays (**ELISAs**) and immunochromo graphic strips are now available for quick detection of the exotoxin from the

cultured isolates. A rapid diagnostic test based on polymerase chain reaction(PCR) for the toxin gene (*tox*) is another new direct assay of patient specimens, prior to culture and isolation of the organism.



Diphtheria toxin

This exotoxin produced by strains carrying bacteriophages with the ***tox* gene** – inhibits protein biosynthesis in all eukaryotic cells. The toxin has two components: *subunit A*,which has the adenosine diphosphate ribosylating activity, and *subunit B*, which binds the toxin to cell surface receptors. Essentially, the toxin blocks protein synthesis of host cells by inactivating an elongation factor. Macroscopically, its action on the respiratory mucosa results in the production of a grey, adherent pseudomembrane comprising bacteria, fibrin and epithelial and phagocytic cells. This may obstruct the airway, and the patient may die of asphyxiation. When the toxin permeates into the blood stream, it acts systemically, affecting motor nerves of the myocardium and the nervous system.

The toxin can be converted to a **toxoid** (i.e. made nontoxic but still antigenic) by treatment with formaldehyde; the toxoid can then be used for prophylactic immunization – the first component of the diphtheria–tetanus–pertussis (DTP) vaccine. **Antitoxin**, produced by injecting the toxin into horses, neutralizes the toxin

Pathogenicity

C. diphtheriae is the agent of **diphtheria**; it usually affects the mucosa of the upper respiratory tract, and sometimes the skin. Cutaneous infections are especially seen in the tropics and are

usually mixed infections with *Staphylococcus aureus* and/or *Streptococcus pyogenes*. Serious systemic manifestations are the result of the absorption of the exotoxin.

Tonsillitis Diphtheria

The symptoms of diphtheria

- Pharyngitis, fever, swelling of the neck or area surrounding the skin lesion.

-Diphtheritic lesions are covered by a pseudomembrane. The toxin is distributed to distant organs by the circulatory system and may cause paralysis and congestive heart failure.

Treatment and prevention

In the acute phase, supportive therapy to maintain the airway is critical. Antitoxin is given to neutralize the toxin and penicillin to kill the organisms. Antibiotics have little effect once the toxin has spread, but will eliminate the toxigenic focus of bacteria. In epidemic outbreaks, carriers are given either penicillin or erythromycin.

Immunization is highly effective in preventing diphtheria.A special test **(Schick test**) is used to demonstrate immunity. Here, the circulating level of antibody after immunization (or clinical/subclinical infection) is assessed by inoculating a standardized dose of the toxin.

Skin test = Schick test

To determine whether The patient is susceptible to diphtheria infection or not by detecting the presence or absence of antibodies.

Procedures:

1. 0.1 ml of toxin is injected intradermally in one arm.
2. 0.1 ml of heated (inactivated) toxin as a control is injected in the other arm.
3. Read after 24-48 hours.

Positive: (Susceptible)Redness and swelling that increases for several days and then fades, leaving brownish pigmented area. The control site shows no reaction.

Negative:(Not susceptible) Neither injection site shows any reaction).

22 abed elkader elottol

Other Corynebacteria

Corynebacterium ulcerans is responsible for diphtheria-like throat lesions, but it does not cause toxaemia .*Corynebacterium* is the only true coryne form organism in the oral cavity. It resembles a whip ('whip-handle cell'), with a short, fat body and a long filament at one end.

Diphtheroids

Bacilli that morphologically resemble diphtheria bacilli are called diphtheroids (e.g. *Corynebacterium hofmannii*, *Corynebacterium xerosis*). They are normal inhabitants of the skin and conjunctiva and are occasional opportunistic pathogens in compromised patients (e.g. endocarditis in prosthetic valves).

Propionibacteria

Propionibacteria are obligate anaerobic, Gram-positive rods, sometimes called '**diphtheroids**' for the reasons given *Propionibacterium acnes* is part of the normal skin flora and may also be isolated from dental plaque. The pathogenesis of facial acne is closely related to the lipases produced by *P.acnes*, hence the name. A new member of this genus is *Propionibacterium propionica*, morphologically similar to *Actinomyces israelii* .

General structure and classification of viruses

General properties of viruses:

1. Viruses are smaller than bacteria, they range in size between 20-300 nanometer (nm) (Table 2-1).

2. Viruses contain only one type of nucleic acid, either DNA or RNA, but never both.

3. Viruses consist of nucleic acid surrounded by a protein coat. Some viruses have additional lipoprotein envelope.

4. Viruses lack cellular organelles, such as mitochondria and ribosomes.

5. Viruses are obligate cellular parasites. They replicate only inside living cells.

6. Viruses replicate through replication of their nucleic acid and synthesis of the viral protein.

7. Viruses do not multiply in chemically defined media.

8. Viruses do not undergo binary fission.

Virus is a broad general term for any aspect of the infectious agent and includes:
• the infectious or inactivated virus particle

• viral nucleic acid and protein in the infected cell

Virion is the physical particle in the extra-cellular phase which is able to spread to new host cells; complete intact virus particle is able to spread to new host cells; complete intact virus particle.

Table (2-1) : Comparison between viruses and bacteria

Comparison between viruses and bacteria

No.	Property	Viruses	Bacteria
1	Size	20-300 nm	1000 nm
2	Genome (type of nucleic acid)	DNA or RNA but not both	DNA and RNA
3	Cell wall	Envelope present in some viruses	Cell wall
4	Ribosomes	No ribosomes	Ribosomes
5	Multiplication by binary fission	_	+
6	Sensitivity to antibiotics	_	+
7	Growth in culture media	Grow only in living host cell	Grow in culture media

The structure of viruses:

1. Viral nucleic acid:

The viral nucleic acid is located internally and can be either single- or double-stranded RNA or DNA. The nucleic acid can be either linear or circular. The DNA is always a single molecule; the RNA either can exist as a single molecule or in several pieces (segmented).

• Some RNA viruses are positive polarity and others are negative polarity.

• Positive polarity is defined as an RNA with same base sequence as the mRNA. (Positive strand RNA)

• Negative polarity has a base sequence that is complementary to the mRNA. (Negative strand RNA) (Figure 2-1)

2. Capsid:

The protein shell, or coat, that encloses the nucleic acid genome and mediates the attachment of the virus to specific receptors on the host cell surface.

3. **Capsomeres:**

Morphologic units seen in electron microscope. Each capsomere, consisting of one or several proteins.

Naked viruses are composed of nucleic acid + capsid (nucleocapsid)

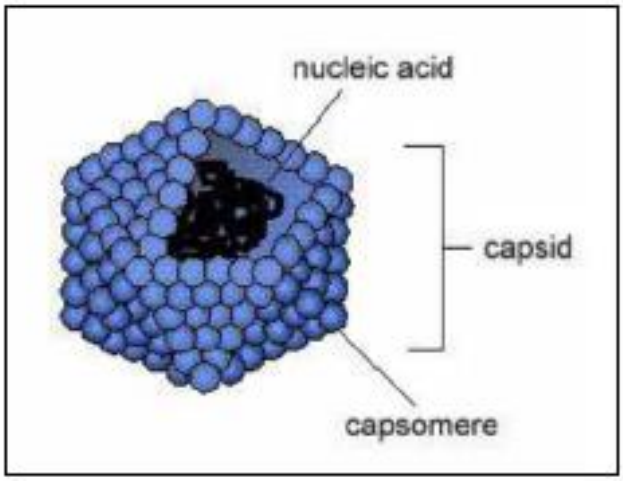

Figure 2-1 Naked virus composition

4. Viral envelope:

The envelope is a lipoprotein membrane composed of lipid derived from the host cell membrane and protein that is virus- specific. Furthermore, there are frequently glycoproteins in form of spike-like projections on the surface, which attach to host cell receptors. Matrix protein mediates the interaction between the capsid proteins and envelope. The presence of an envelope confers instability on the virus Enveloped viruses NA + capsid + envelope

The whole virus particle is called virion. (Figure 2-2)

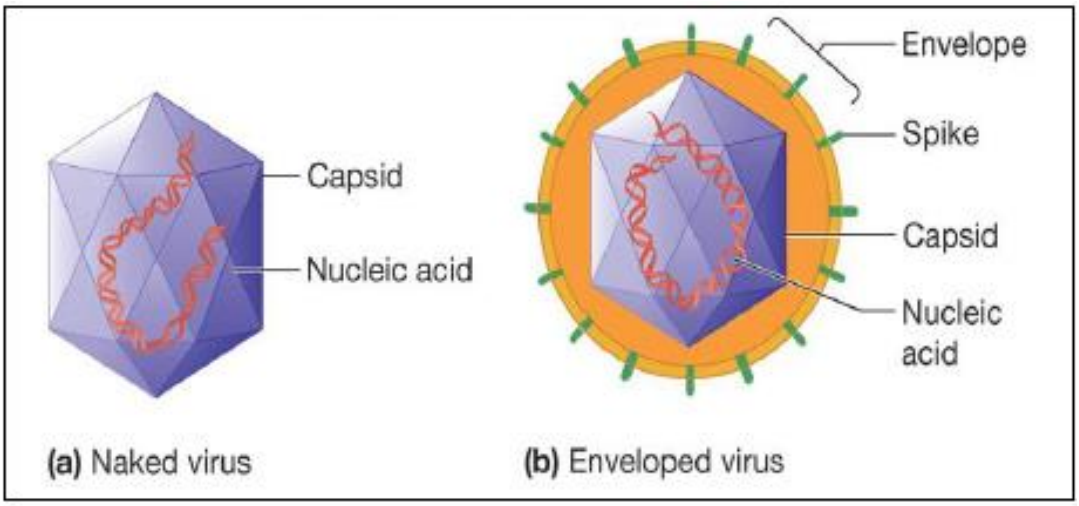

Figure 2-2 illustrate the difference between enveloped virus and naked virus

Reaction to physical and chemical agents:

1. Heat and cold: Viral infectivity is generally destroyed by heating at 50-60 C^0 for 30 mint. Viruses can be preserved at -90 C0 or -196 C^0 (liquid nitrogens).

2. PH: Viruses can be preserved at physiological PH (7.3).

3. Ether susceptibility: Ether susceptibility can be used to distinguish viruses that possess an envelope from those that do not.

4. Detergents: Nonionic detergents solubilize lipid constituents of viral membranes. The viral proteins in the envelope are released Anionic detergents also solubilize viral envelopes; in addition, they disrupt capsids into separated polypeptides.

Viral Replication:

Steps in Viral Replication:

A. Attachment:

This is the first step in viral replication. Surface proteins of the virus interact with specific receptors on the target cell surface.

B. Penetration:

Enveloped with the viruses (e.g., HIV, influenza virus) penetrate cells through fusion of the viral envelope host cell membrane. Non-enveloped viruses penetrate cells by translocation of the virion across the host cell membrane or receptor mediated endocytosis.

C. Un-coating:

This process makes the nucleic acid available for transcription to permit multiplication of the virus.

D. Transcription and Translation:

The fact that viruses must use host cellular machinery to replicate and make functional and structural proteins. Assembly and Release. The process of virion assembly involves bringing together newly formed viral nucleic acid and the structural proteins to form the nucleo-capsid of the virus

E. Virus Shedding:

This is a necessary step to maintain a viral infection in populations of hosts. Shedding usually occurs from the body surfaces involved in viral entry. Shedding occurs at different stages of disease depending on the particular agent involved.

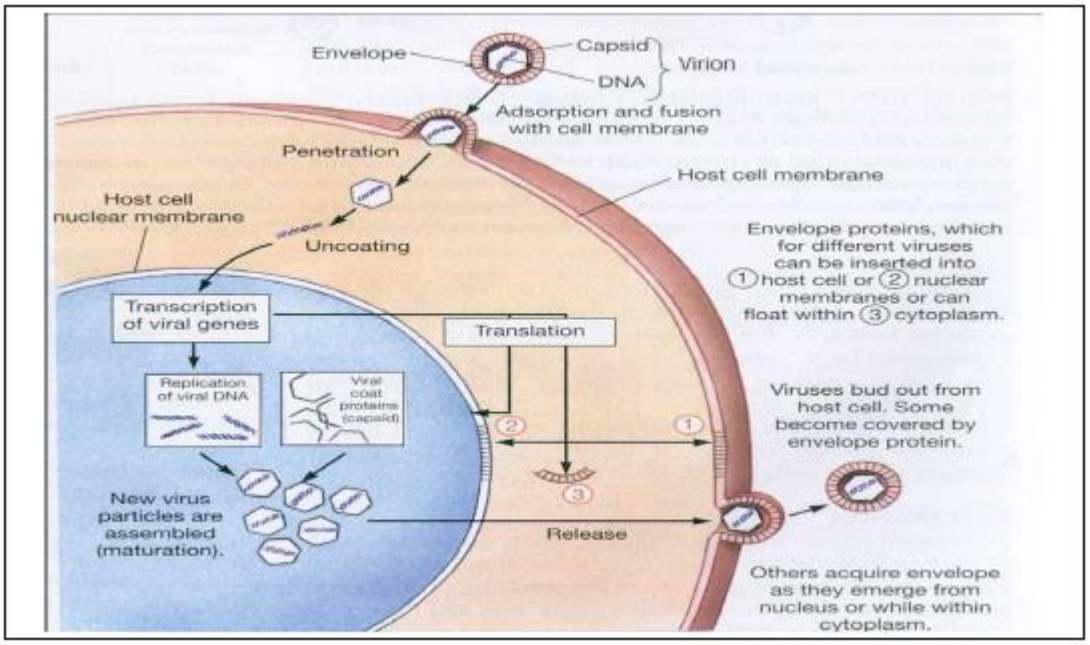

Figure (2-4) steps of viral replication

Routs of infection

- Inhalation; e.g influenza viruses
- Ingestion: polioviruses
- Parenteral: AIDs
- Trans placental, cytomegalovirus, rubella.

Viral Spread and Cell Tropism

Many viruses produce disease at sites distant from their point of entry. Spread within the host . Mechanisms of viral spread vary, but the most common route is via the bloodstream or lymphatics. The presence of virus in the blood is called viremia.

Mechanisms of viral injury

1. Inhibits host cell DNA, RNA or protein synthesis e.g. Poliovirus.
2. Direct cell killing by damaging host cell membrane e.g. Rhinoviruses.
3. Induce Immune reaction e.g hypersensitivity reaction in respiratory syncytial viruses.
4. Damage host defiance mechanism e.g. respiratory epithelium predisposes to the pneumonia
5. Induce cell proliferation & transformation result in neoplasia e.g. HBV, EBV.

A successful anti-viral drug should:

The life cycle of a virus comprises several stages such as binding to the cell surface, replication, protein synthesis etc. and all of these stages may be the target of anti-viral drugs. Antiviral drugs specifically inhibit one or more steps of virus replication without causing unacceptable side effects. Because of the close interaction between virus replication and normal cellular metabolism, it was originally thought too difficult to interrupt the virus replicative cycle without adversely affecting the host cell metabolism.

The mechanism of action vary among antiviral:

1. Nucleoside and nucleotide Analogs:

The majority of available antiviral agents are nucleoside analogs. They inhibit nucleic acid by inhibition of polymerases essential for nucleic acid replication. In addition, some analogs can be incorporated into the nucleic acid and block further synthesis or alter its function. Example for nucleoside analogs include acyclovir , lamivudine ,ribavirin and zidovudine : AZT Acyclovir (Zovirax) represents a major breakthrough in the treatment of herpes virus infections.

2. Reverse transcriptase inhibitor:

It acts by binding directly to reverse transcriptase and disrupting the enzyme's catalytic site, for example Nevirapine.

3. Protease inhibitor:

Saquinavir was the first protease inhibitor to be approved for treatment of HIV infection, which inhibit viral protease that is required for the last stage of replicative cycle. Inhibition of the protease yields noninfectious virus particles.

Vaccine:

A vaccine is a biological preparation that provides active acquired immunity to a particular disease. A vaccine typically contains an agent that resembles a disease-causing microorganism and is often made from weakened or killed forms of the microbe,

Type of viral vaccine:

There are four categories of vaccines in clinical trials: **WHOLE VIRUS**, **PROTEIN SUBUNIT**, **VIRAL VECTOR** and **NUCLEIC ACID** (RNA AND DNA).

1. Attenuated live viral vaccines

These attenuated viruses can infect and replicate in the recipient and produce a protective immune response without causing disease. Live attenuated viral vaccines can often confer lifelong immunity after one immunization series (.

Live-attenuated vaccines

- Measles, mumps, rubella (MMR combined **vaccine**)
- Rotavirus.
- Smallpox.
- Chickenpox.
- Yellow fever

2. Killed (inactivated) viral vaccines

Killed viral vaccines contain either whole virus particles, inactivated by chemical or physical means, or some component(s) of the virus. They do not generally produce lifelong immunity following one immunization series (e.g.: Rabies vaccine, Injectable poliomyelitis vaccine (IPV)

3. Recombinant-produced antigens

Application of a recombinant DNA strategy to develop new vaccines (Subunit vaccines use pieces of the pathogen - often fragments of protein). This approach has made possible a safe and effective recombinant vaccine against hepatitis B virus, which has replaced the vaccine derived from the plasma of hepatitis B virus-infected individuals.

4. Nucleic acid

Nucleic acid vaccines use genetic material – either RNA or DNA – to provide cells with the instructions to make the antigen. In the case of COVID-19, this is usually the viral spike protein. Once this genetic material gets into human cells, it uses our cells' protein factories to make the antigen that will trigger an immune response.

Type of Vaccines

Herpesviruses OR Herpesviridae

Classification

Herpesviruses are divided into three groups: The **α herpesviruses**, herpes simplex virus types 1 and 2, and varicella-zoster virus, have a short replicative cycle and have a broad host range; **β herpesviruses**, cytomegalovirus, and human herpesviruses 6 and 7, with a long replicative cycle and restricted host range; and **γ herpesviruses**, Epstein-Barr virus and human herpesvirus 8, with a very restricted host range.

A. Alphaherpesviruses - HSV-1, HSV-2, VZV

B. Betaherpesviruses - CMV, HHV-6, HHV-7

C. Gammaherpesviruses - EBV, HHV-8

Nine herpesvirus types are known to primarily infect humans, at least five of which – herpes simplex viruses 1 and 2 (HSV-1 and HSV-2, also known as HHV-1 and HHV-2; both of which can cause orolabial herpes and genital herpes), varicella zoster virus (or HHV-3; the cause of chickenpox and shingles), Epstein–Barr virus (EBV or HHV-4; implicated in several diseases, including mononucleosis and some cancers), and human cytomegalovirus (HCMV or HHV-5) – are extremely widespread among humans.

More than 90% of adults have been infected with at least one of these, and a latent form of the virus remains in almost all humans who have been infected. The less-common human herpesviruses are human herpesvirus 6A and 6B (HHV-6A and HHV-6B), human herpesvirus 7 (HHV-7), and Kaposi's sarcoma-associated herpesvirus (KSHV, also known as HHV-8)

General Biology of Human Herpesviruses

Of the more than 100 known herpesviruses, 9 routinely infect only humans:

- **Herpes simplex virus types 1 and 2** (HSV-1 and HSV-2 both of which can cause orolabial herpes and genital herpes.

- **Varicella-zoster virus (cause of chickenpox and shingles OR belt of fire).**

Symptoms of shingles

The main symptom of shingles is pain, followed by a rash that develops into itchy blisters, similar in appearance to chickenpox. New blisters may appear for up to a week, but a few days after appearing they become yellowish in color, flatten and dry out. Shingles is most common in people over the age of 50 years. However, the virus may reappear in people of all ages who have previously had chickenpox.

Causes of shingles

Most people have chickenpox in childhood, but after the illness has gone, the varicella-zoster virus remains dormant (inactive) in the nervous system. The immune system keeps the virus in check, but later in life it can be reactivated and cause shingles. It's possible to have shingles more than once, but it's very rare to get it more than twice. It's not known exactly why the shingles virus is reactivated at a later stage in life, but most cases are thought to be caused by having lowered

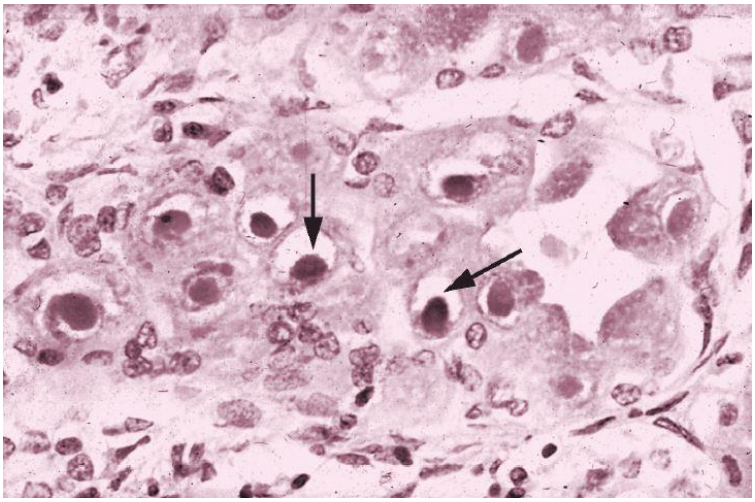
immunity (protection against infections and diseases). Shingles typically resolve within 2 to 4 weeks, and most young, healthy individuals make a full recovery. Approximately 1-4 percent of people who develop shingles require hospitalization for complications.

- **Cytomegalovirus**: causes three clinical syndromes. (1) Congenital cytomegalovirus infection (when symptomatic) causes hepatosplenomegaly, retinitis, rash, and central nervous system involvement.

  Human cytomegalovirus (HCMV) is a ubiquitous virus infection with worldwide distribution. The virus is the most significant infectious cause of congenital disease, an important opportunist in the immunocompromised host and an occasional cause of febrile illness as well as infectious mononucleosis in the general population. CMV is transmissible to the fetus via the placenta, and is an important cause of neonatal morbidity and mortality.

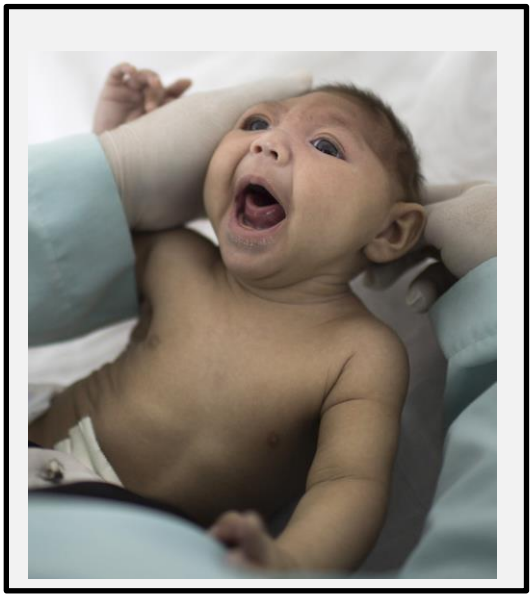
  HCMV infection in humans initiates when exposure to virus infected body fluids overcomes innate immune barriers and sustains replication and dissemination. These events occur most frequently at mucosa sites. A systemic infection takes place where virus can be detected in a peripheral blood mononuclear cell (PBMC

leukocytes T cells, B cells, NK cells) and monocytes) that are responsible for dissemination to salivary glands and kidneys.

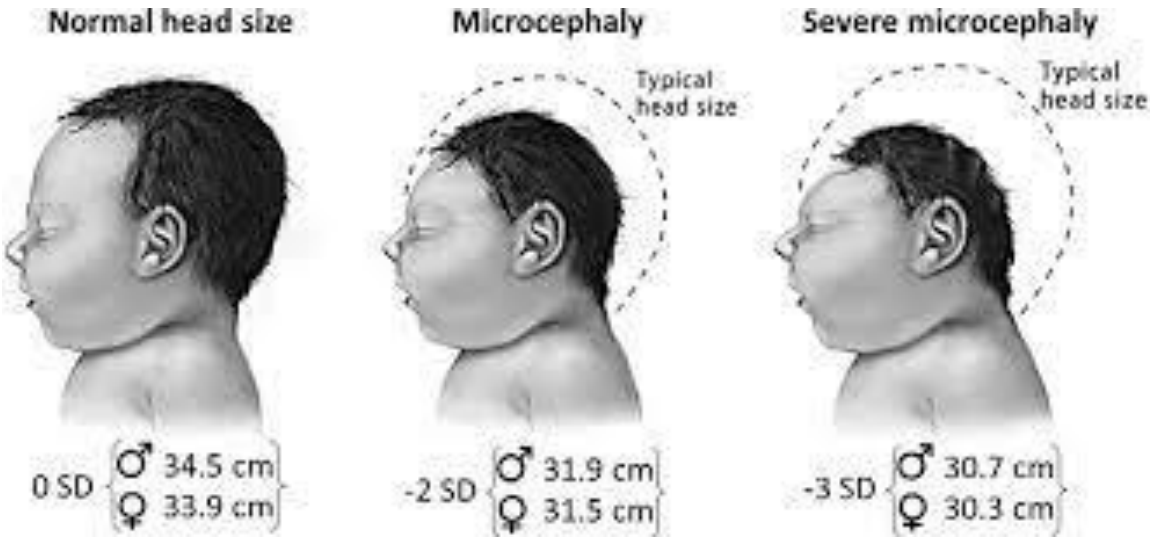


The following signs and symptoms are more common in babies who have congenital CMV and who are sick at birth:

- Premature birth
- Low birth weight
- Yellow skin and eyes (jaundice)
- Enlarged and poorly functioning liver
- Purple skin splotches or a rash or both
- Abnormally small head (microcephaly)
- Enlarged spleen
- Pneumonia



Abnormally small head (microcephaly)

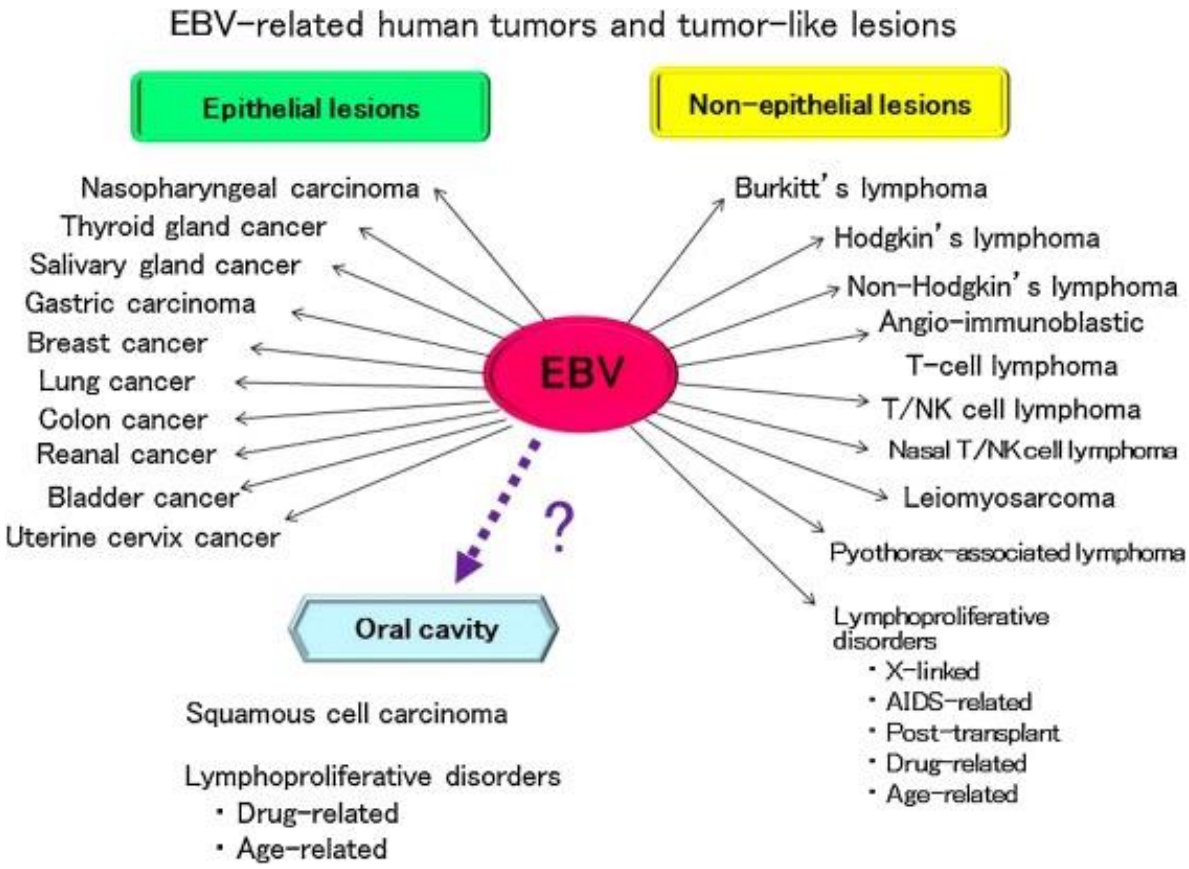


Normal and Abnormally small head (microcephaly)

- **Epstein-Barr virus**: **causes classic mononucleosis**

The Epstein-Barr virus (or EBV) have been consistently found to be associated with some types of B-cell lymphomas. B lymphocytes and epithelial cells are the major sites for EBV infection in the human host. EBV binding to B cells is mediated by CD2 1 , also known as complement receptor 2 (CR2). Over 900/o of adults are infected with EBV Infection is most common between the ages of 2 and 4 years and at around age 1 5 years.

In contrast to B-cell entry, EBV entry into epithelial cells occurs at the cell surface in the absence of endocytosis. In addition to CD2 l , which is expressed on tonsilar epithelial cells, suggesting the gp3 50/220 interaction with CD2 1 may be important for epithelial cell infection,688 BMRF2 may also have a role in epithelial entry.



Other Human Herpes Viruses

- **Human herpesvirus 6 and 7**

Properties of HHV-6 and 7

• Belong to the beta-herpes virus subfamily of herpes viruses

• Double stranded DNA genome of 170 kbp

• The main target cell is the T-lymphocyte, although B-lymphocytes may also be infected.

• HHV-6 and HHV-7 share limited nucleotide homology and antigenic cross-reactivity.

• It is thought that HHV-6 and HHV-7 are related to each other in a similar manner to HSV-1 and HSV-2.

Clinical Manifestations

• Primary HHV-6 infection is associated with **Roseola infantum** , which is a classical disease of childhood. The virus can enter the body through the nose and mouth. It is spread when a child breathes in droplets that contain the virus after an infected person coughs, sneezes, talks, or laughs.

• Most cases occur in infants between the ages of 4 months and two years.

• A spiking fever develops over a period of 2 days followed by a mild rash. The fever is high enough to cause febrile convulsions.

• There are reports that the disease may be complicated by encephalitis.

- **Human Herpes Virus 8**

• Belong to the gammaherpesviruses subfamily of herpesviruses

• Originally isolated from cells of Kaposi’s sarcoma (KS). Kaposi's sarcoma is a type of cancer that forms in the lining of blood and lymph vessels. The tumors (lesions) of Kaposi's sarcoma typically appear as painless purplish spots on the legs, feet or face. Lesions can also appear in the genital area, mouth or lymph nodes.

• HHV-8 DNA is found in almost 100% of cases of Kaposi’s sarcoma

• Most patients with KS have antibodies against HHV-8 .

• Unlike other herpes viruses, HHV-8 does not have a ubiquitous distribution.

Paramyxovirus virus

One of a group of RNA viruses that are predominantly responsible for acute respiratory diseases and are usually transmitted by airborne droplets. The paramyxoviruses include the agents of mumps, measles (Rubeola virus), Rubella, RSV (respiratory syncytial virus), and parainfluenza.

1- Mumps

Mumps is caused by the mumps virus (MuV). Humans are the only natural host of the mumps virus. MuV's genome is made of RNA and contains seven genes that encode nine proteins.

Clinical aspects: The onset is marked by malaise and fever followed within 24 hours by a painful enlargement of one or both parotid glands; the other salivary glands are less often affected. In most cases, the swelling subsides within a few days and recovery is uneventful.

Central nervous system: The incidence of 'aseptic' meningitis is higher after mumps than after any other acute viral infection of childhood. Rates of 0.3–8.0 per cent have been reported in the USA. This complication almost always resolves without sequelae. Postinfection encephalitis is, however, more serious and carriesan appreciable mortality.

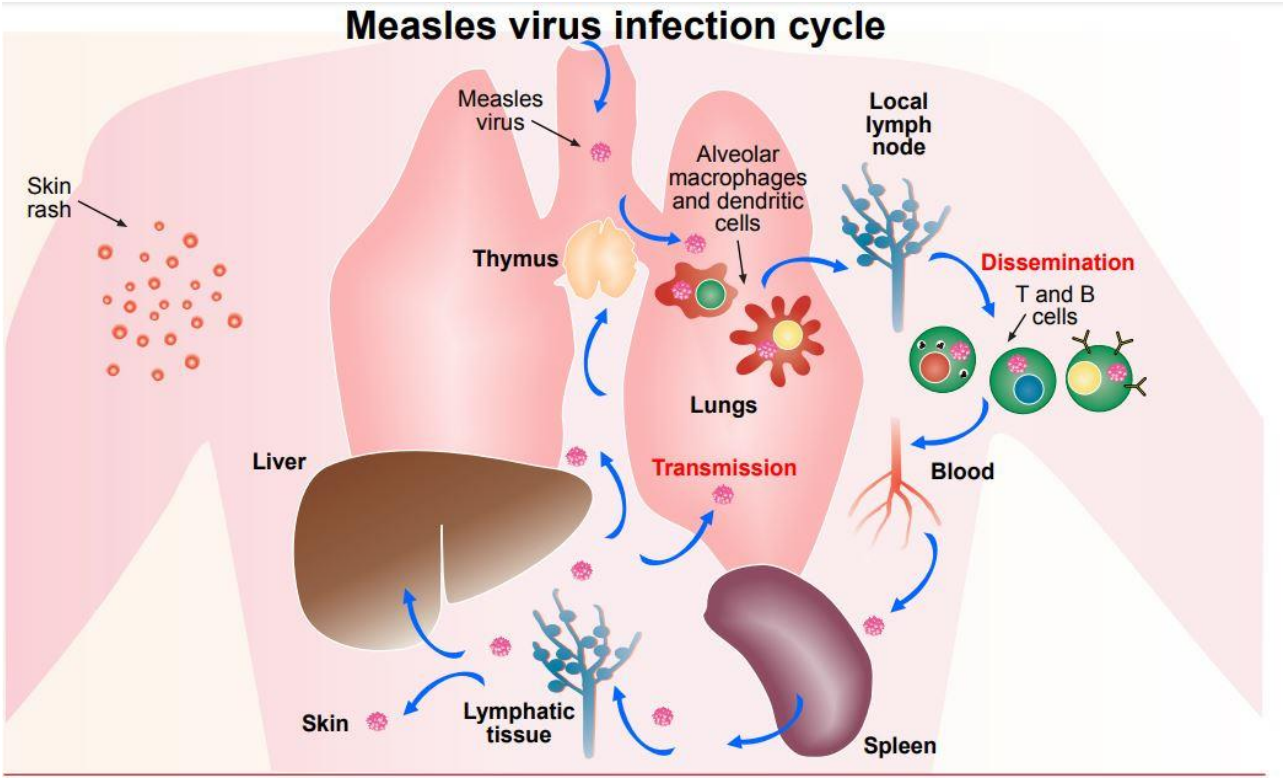
Pathogenesis: The infection is spread in saliva and secretions from the respiratory tract, and is acquired by the respiratory route, either by aerosol or hand contact. The incubation period is 14-21 days. Viraemia during the acute phase is followed by generalized spread to various organs, including the parotid gland. Virus is shed for several days before and after the first symptoms, not only from the respiratory tract but also in the urine. Mumps virus binds to sialic acid to enter the polarized epithelial cells in the upper respiratory tract from both sides.

2- Measles

Measles is a highly contagious infectious disease caused by measles virus. Symptoms usually develop 10–12 days after exposure to an infected person and last 7–10 days. Over 1 million mal-nutrient children die each year of measles in the developing world.

Measles target cells

The main target cells are immune cells such as T and B cells, macrophages and dendritic cells that express CD150 (or SLAM) which serves as an entry receptor. CD46 expressed on most cells can also be used by some wild-type strains. Measles virus infects epithelial cells using nectin-4.Measles virus can also penetrate the brain, but is usually controlled. Infection of pulmonary epithelial cells permits transmission to other hosts.



Symptoms of measles

The initial symptoms of measles develop around 10 days after you're infected.

These can include:

- cold-like symptoms, such as a runny nose, sneezing and a cough
- sore, red eyes that may be sensitive to light
- a high temperature (fever), which may reach around 40C
- small greyish-white spots on the inside of the cheeks

3- Para-influenza

The human parainfluenza viruses (HPIV) are the second most common causes of respiratory tract disease in infants and children. There are four types of HPIVs, known as HPIV-1, HPIV-2, HPIV-3 and HPIV-4. HPIV-1 and HPIV-2 may cause cold-like symptoms, along with croup (laryngotracheobronchitis) in children.

HPIV-3 is associated with bronchiolitis, bronchitis, and pneumonia. HPIV-4 is less common than the other types, and is known to cause mild to severe respiratory tract illnesses.

Symptoms of of human para-influenza viruses

While symptoms may vary child-to-child, the most common include:

- runny nose
- redness or swelling of the eyes
- barky cough
- noisy, harsh breathing
- wheezing
- fever
- irritability
- decreased appetite
- vomiting
- diarrhea

Miscellaneous microorganism

a-Rickettsia and Chlamydia.

b-Mycoplasma

c-Veillonella

Chlamydiae, Rickettsiae and mycoplasmas are a miscellaneous group of organisms with properties common to both bacteria and viruses.

Chlamydiae

The chlamydiae are a group of microorganisms related to Gram-negative bacteria . However, unlike bacteria, they are unable to grow on inanimate culture media. Their main characteristics include the following

• Larger than most viruses and hence visible by light microscopy.

• Both DNA and RNA are present.

• Obligate intracellular parasites with a complex growth cycle.

• Sensitive to tetracycline, erythromycin, sulphonamides.

There are three species in the genus *Chlamydia*:

1. *Chlamydia trachomatis* is an agent of many diseases

2. *Chlamydia pneumoniae* causes acute respiratory tract infection, including sore throat, mild pneumonia and fever in humans.

3. *Chlamydia psittaci* primarily causes disease **(psittacosis)** in birds such as pet parrots and budgerigars, from which humans contract the infection. The human infection, also known as psittacosis, takes the form of a primary a typical pneumonia.

Chlamedia trachomatis : Causes a spectrum of diseases. the real number of chlamydia infections every year may be closer to 3 million.

Ocular infections - Trachoma is a chronic conjunctivitis caused by Chlamydia trachomatis. It was once the most important cause of blindness worldwide, The infection can be spread from eye to eye by fingers, shared towels or cloths, coughing and sneezing and eye-seeking flies. Symptoms include mucopurulent ocular discharge, irritation, redness, and lid swelling. Newborns can also develop chlamydia eye infection through childbirth

_ Genital infections – non-specific urethritis, the most common sexually transmitted disease in the UK . Most people who are infected have no symptoms . In the tropics, it causes lymphogranuloma venereum

Chlamydia is caused by a bacterial infection. The only true cure for this type of infection is antibiotics.

But some alternative treatments may help ease symptoms, untreated chlamydia can lead to long-term complications, including fertility problems and chronic inflammation.

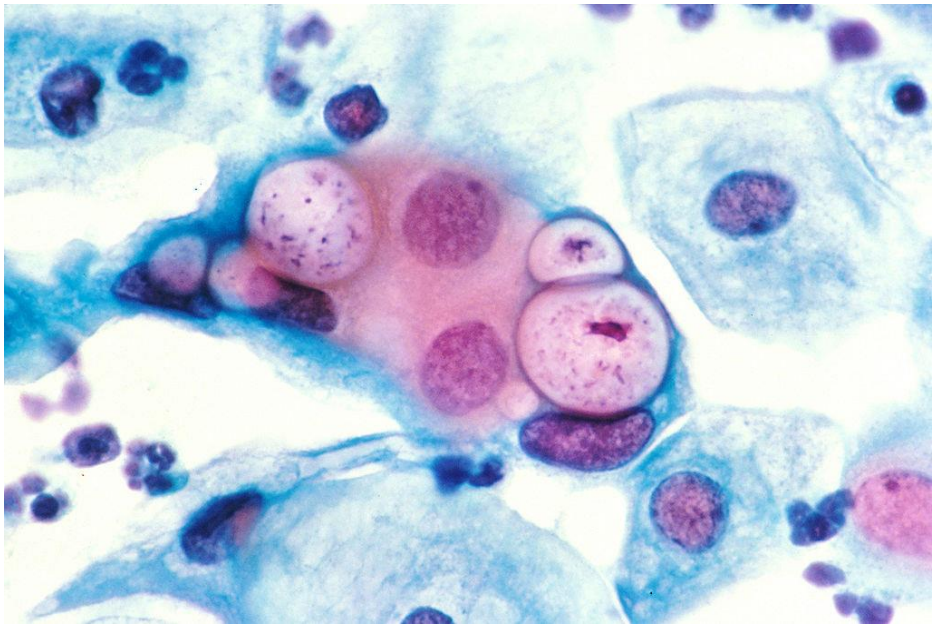


Fig 1:-Pap Smear Description: Human pap smear showing chlamydia in the vacuoles at 500x and stained with H&E.

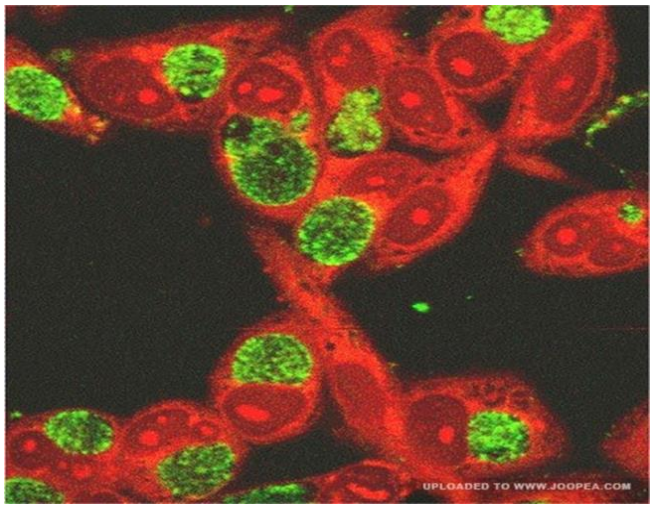
Pneumonia – in neonates. Newborn babies can acquire chlamydia from their mother during .birth

Culture and diagnosis

Identified by tissue culture (e.g.Hela cells) ,serology (complement fixation tests)and fluorescent antibody staining of smears from the lesion.



Hela cells :-is an immortal cell line used in scientific research. It is the oldest and most commonly used human cell line. The line is derived from cervical cancer cells taken on 1951, from Henrietta Lacks, a 31-year-old African-American, who died of cancer. The cell line was found to be remarkably durable and prolific, which allows it to be used extensively in scientific study

Antibiotic sensitivity

Tetracycline is effective for all chlamydial infections.

Rickettsiae

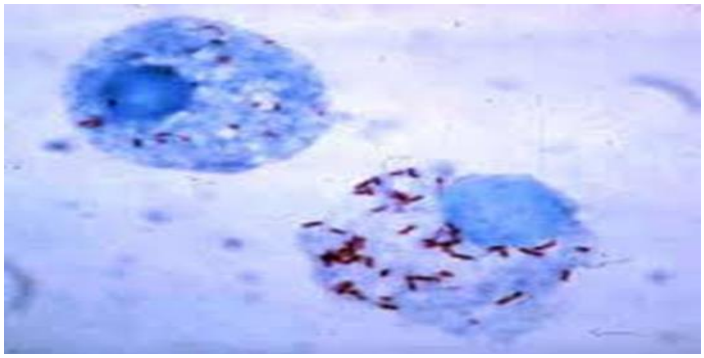
Rickettsiae are pleomorphic organisms, smaller than bacteria but resembling them structurally and metabolically, including cell wall formation. They, like Chlamydia and viruses. The best-known human rickettsial disease is typhus, which spreads wildly in conditions of malnutrition _Coccobacilli, with a multilayered outer cell wall resembling that and poverty. Rickettsiae are of Gram-negative bacteria cell wall. Rickettsias are generally sensitive to environmental exposure, although R. typhi can survive several years in dried flea droppings

_Obligate intracellular parasites that replicate by binary fission .

_Visible by light microscope when special stains are used(e.g.Giemsa).

_Able to infect many species, including arthropods, birds and mammals; members of the genus are transmitted to humans via bites of infected arthropods

Sensitive to tetracycline and chloramphenicol.



_

Distribution and Ecology of Rickettsial Diseases

The Role of Arthropod Vectors

The rickettsial life cycle depends upon a complex exchange between blood-sucking arthropod hosts and vertebrate hosts. Eight tick genera, two fleas, and one louse are involved in the spread of rickettsias to humans.

General Factors in Rickettsial

Pathology and Isolation

A common target in rickettsial infections is the endothelial lining of the small blood vessels. The bacteria recognize, enter, and multiply within endothelial cells, causing necrosis of the vascular lining

Among the immediate pathologic consequences are vasculitis, perivascular infiltration by infl ammatory cells, vascular leakage, and thrombosis. These pathologic effects are manifested by skin rash edema, hypotension, and gangrene. Intravascular clotting in the brain accounts for the stuporous mental changes and other neurological symptoms that sometimes occur

There are two genera within the Rickettsieae:

Rickettsia and Coxiella.

Rickettsia

Rickettsial diseases include:

Epidemiology of Epidemic Typhus Humans are the sole hosts of human body lice and the only reservoirs of *R. prowazekii.* The louse spreads infection by defecating into its bite wound or other breaks in the skin. Infection of the eye or respiratory tract can take place by direct contact or inhalation of dust containing dried louse feces, but this is a rarer mode of transmission.

TABLE 21.2 Characteristics of Major Rickettsias Involved in Human Disease

Disease Group	Species	Disease	Vector	Primary Reservoir	Mode of Transmission to Humans	Where Found
Typhus	*Rickettsia prowazekii*	Epidemic typhus	Body louse	Humans	Louse feces rubbed into bite; inhalation	Worldwide
	R. typhi (mooseri)	Murine typhus	Flea	Rodents	Flea feces rubbed into skin; inhalation	Worldwide
Spotted Fever	*R. rickettsii*	Rocky Mountain spotted fever	Tick	Small mammals	Tick bite; aerosols	North and South America
	R. akari	Rickettsialpox	Mite	Mice	Mite bite	Worldwide
Scrub Typhus	*Orientia tsutsugamushi*	—	Immature mite	Rodents	Bite	Asia, Australia, Pacific Islands
Human Ehrlichiosis	*Ehrlichia chaffeensis*	Human monocytic ehrlichiosis	Tick	—	Tick bite	Similar to Rocky Mountain spotted fever
Human anaplasmosis	*Anaplasma phagocytophilum*	Human granulocytic anaplasmosis	Tick	Deer, rodents	Tick bite	Unknown

:Rocky Mountain Spotted Fever

Epidemiology and Pathology

The rickettsial disease with greatest impact on people living in North America is Rocky Mountain spotted fever ,etiologic agent *Rickettsia rickettsii* in smears from infected animals and patients and later discovered that it was transmitted by ticks.

Pathogenesis and Clinical Manifestations of Spotted Fever

After 2 to 4 days incubation, the first symptoms are sustained fever, chills, headache, and muscular pain. Early diagnosis can be made by staining rickettsias directly in a tissue biopsy using fluorescent antibodies. Isolating rickettsias from the patient's blood or tissues is desirable, butit is expensive and requires specially qualified personnel and laboratory facilities. Specimens taken from the rash lesions are suitable for PCR assay, which is very specific and sensitive and can circumvent the need for culture.

Coxiella

Coxiella burnetii, an organism closely resembling rickettsiae,. Rickettsial diseases include:
Typhus, (typhus fever)
Typhus group of infectious diseases that include epidemic typhus, scrub typhus, and murine

typhus. Common symptoms include fever, headache, and a rash.
Typically these begin one to two weeks after exposure Usually Q fever presents as a 'non-bacterial' pneumonia, but lesions may be seen in the brain and other organs, including the heart, with resultant infective endocarditis.

Culture and diagnosis

Isolation of most rickettsias from clinical specimens requires a suitable live medium and specialized laboratory facilities, including controlled access and safety cabinets. The usual choices for routine growth and maintenance are the yolk sacs of embryonated chicken eggs, chick embryo cell cultures, and, to a lesser extent mice and guinea pigs.• Serology: rising titer of antibody in patients sera.

Antibiotic sensitivity: Tetracycline or chloramphenicol.

Mycoplasmas

Mycoplasmas are the smallest prokaryotes capable of binary fission, and they grow, albeit slowly, on inanimate media. Mycoplasmas are indeed wall-less bacteria, without the peptidoglycan cell wall but bound by a plasma membrane consisting of lipids and sterols (including cholesterol). Hence, they are highly pleomorphic. Analysis of *Mycoplasma* genome sequences (16SrDNA) suggests that these organisms are most closely related to *Bacillus–Lactobacillus* and *Streptococcus* sub groups of Gram positive bacteria. The most important species of the genus *Mycoplasma* is *Mycoplasma pneumoniae*, which causes**:**

_A common pneumonia, atypical pneumonia

_ Mucocutaneous eruptions, including the oral mucosa

_ Haemolytic anaemia.

Mycoplasma pneumoniae

Primary atypical pneumonia

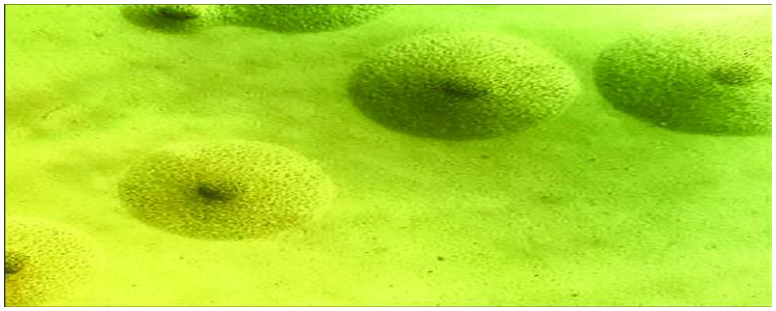
Primary atypical pneumonia takes the form of fever, non productive cough, severe headache, weakness and tiredness. The acute illness lasts for about 2 weeks, but in a majority, the symptoms last longer.

Mucocutaneous eruptions

M. pneumoniae may cause skin rashes and ulcerations of both the oral and vaginal mucosa.. The skin lesions, which often affect the extremities, have a target or iris appearance(**target lesions**). In the oral mucosa, erythematous patches may appear first, quickly becoming bullous and erosive. This leads to extensive blood encrustations, especially the labial lesions. When the oral ulceration is associated with the skin rash and conjunctivitis, it is called **Stevens–Johnson syndrome**.

Culture and diagnosis

Mycoplasma can be cultured in special media but is a slow grower (about 10 days); the colonies have a characteristic fried-egg' appearance. Immunofluorescence of colonies transferred to glass slides is useful (as they do not take up the Gram stain well).Serology is useful as the culture results are delayed. Complement fixation testing for *M. pneumoniae* antibodies is diagnostic.



Antibiotic sensitivity: Tetracycline for adults and erythromycin for children.

Oral mycoplasmas

Mycoplasmas have been isolated from saliva, oral mucosa and dental plaque, but their significance is not clear. The oral species are poorly characterized and include *Mycoplasma buccale*, *Mycoplasma orale* and *Mycoplasma salivarium*. The latter two species have been isolated from salivary glands and are thought to play a role in salivary gland hypo function. Estimates of the oral carriage of mycoplasma vary from 6% to 32%.

Veillonella

Veillonella spp. are non-motile, gram-negative diplococci ,anaerobic .

Veillonella is part of the normal flora of the mouth and gastrointestinal tract and may be found in the vagina. *Veillonella* species are common and considered mainly harmless, or even beneficial, colonizers of the mouth from the early years of life onward .V. parvula subsp. parvula is detected in saliva, on the tongue, and in plaques. They are able to utilize lactate produced by *Streptococcus mutans*, and are thus considered as beneficial bacteria in dental .plaques.

Veillonella spp. are often regarded as contaminants; they are often associated with oral infections; bite wounds; head, neck, and various soft tissue infections; and they have also been implicated as pathogens in infections of the sinuses, lungs, heart, bone, and CNS. Recent reports have also indicated their isolation in pure culture in septic arthritis and meningitis**.**

MYCOBACTERIUM TUBERCULOSIS

INTRODUCTION:

Mycobacterium is a genus of Actinobacteria, given its own family, the Mycobacteriaceae. Over 190 species are recognized in this genus. This genus includes pathogens known to cause serious diseases in mammals, including tuberculosis (Mycobacterium tuberculosis) and leprosy (Mycobacterium leprae) in humans. The Greek prefix myco- means "fungus," alluding to the way mycobacteria have been observed to grow in a mold-like fashion on the surface of cultures.

Mycobacteria is an obligate aerobe growing most successfully in tissues with a high oxygen content.(the upper lobe of the lung and the kidney).

- Its cell wall contains several complex lipids (long-chain fatty acids called mycolic acids). It is relatively resistant to acids and alkalis. NaOH is used to concentrate clinical specimens; it destroys unwanted bacteria, human cells, and mucus but not the organism.

They are Facultative intracellular pathogens usually infecting mononuclear .(phagocytes (e.g. macrophages

MORPHOLOGY:

SHAPE - long, slender, straight or slightly curved rod. SIZE - 3 x 0.3 µm , Intracellular., Mycolic acid, waxes & lipids are present in cell wall . The high lipid content (approximately 60%) of their cell wall makes mycobacteria acid-fast and hydrophobic. . Because the cells are hydrophobic and tend to clump together, they are impermeable to the usual stains, e.g. Gram's stain , Neither gram-positive nor .gram-negative

ACID FAST BACILLI: Mycobateria are virtually the only bacteria that are acid-fast because of the presence of mycolic acid and their lipid-rich cell walls, which are relatively impermeable to various basic dyes unless the dyes are combined with phenol. Once stained, the cells resist decolourization with acidified organic solvents and are therefore called "acid-fast". Carbol Fuchsin Stain

CULTURE: Mycobacteria are aerobes, Grow slowly 14-15 hours , Optimum temperature 37 degree C. Do not grow below 25 degree C. pH between 6.4 to 7.0 ,

Grow only in specially enriched media containing egg, asparagine, potatoes, serum .and meat extracts. Colonies appear in 2-6 weeks.

RESISTANCE: Mycobateria can survive in dust for several months in sputum for 20-30 hours. Killed at temperature of 60 degree C for 20 minutes and instantly at .100 degree C. Sensitive to ultraviolet ray and sunlight

Medical classification

Mycobacteria can be classified into three l major groups for purpose of diagnosis and treatment:

1-Tuberculosis: Tuberculosis is a systemic infectious disease involving respiratory, genitourinary and lymphatic systems caused by Mycobacterium tuberculosis complex (Mycobacterium tuberculosis, M. bovis, M. africanum, and M. microti).

Tuberculosis (TB) may be regarded in two categories: active disease or latent infection. The most common form of

I-Active TB is lung disease, but it may invade other organs, so-called "."extrapulmonary TB

*Extrapulmonary tuberculosis (miliary tuberculosis) Disseminated Tuberculosis remains a significant clinical problem because symptoms and signs may be difficult to recognize and to relate to tuberculosis Miliary tuberculosis is a potentially life-threatening type of tuberculosis that occurs when a large number of the bacteria travel through the bloodstream and spread throughout the body

II-latent infection: Many of those who are infected with TB do not develop overt disease. They have no symptoms and their chest x-ray may be normal. tuberculin skin test positive.

2-Nontuberculous mycobacterioses(NTM)

Nontuberculous mycobacteria (NTM) have been commonly implicated as opportunistic pathogens in patients with underlying disease or immunosuppression including AIDS. M. avium complex (M. avium and M. intracellulare) and M. kansashii are most common causes of nontuberculous mycobacterial diseases in humans

3-Leprosy:-. M. leprae is the causative agent of leprosy, an infection of the skin, mucous membranes, and peripheral nerves.

Mycobacterium tuberculosis : It causes TUBERCULOSIS which is the most common cause of death due to bacterial infection worldwide.It is closely related to M. bovis M. tuberculosis is resistant to dehydration and so survives in dried expectorated sputum; this property may be important in its transmission by aerosol

HISTORY In 1882, microbiologist Robert Koch discovered the tubercle bacillus, at a time when one of every seven deaths in Europe was caused by TB.

He Isolated the mammalian tubercle bacillus on Heat Coagulated Bovine Serum and proved its causative role in Tuberculosis. , He received the Nobel Prize in physiology and medicine in 1905 for this discovery.

Diseases caused by Mycobacterium species:

M. leprae - leprosy

M. avium - lung and skin infections in immunocompromised hosts - lymphadenopathy in children - catheter-related infections

M. bovis - Primarily infection among the cattle It infects Tonsils, Cervical nodes. Enter through Intestines – infects the ileocecal region

Transmission and epidemiology : M. tuberculosis is transmitted from person to person by respiratory aerosol, and its initial site of infection is the lung. In the body, it resides within macrophages.

- In developed countries, tuberculosis is almost exclusively a human disease, and most tuberculosis is due to reactivation in elderly, malnourished men. In developing countries, M. bovis is found in cow's milk, which, unless pasteurized, can cause gastrointestinal tuberculosis in humans. The risk of infection and disease is highest among socio-economically disadvantaged people, who have poor housing and poor nutrition. Coughing projects droplet nuclei into the air that contain tubercle bacilli. One cough can release 3,000 droplet nuclei. One sneeze .can release tens of thousands of droplet nuclei

Pre-Disposing Factors: Genetic basis, Age Stress, Nutrition, Co existing infections Eg. HIV. HIV association will lead to rapid spread of tuberculosis. HIV kills CD4+ .T Helper cells which normally inhibit M. tuberculosis

INDIA is the highest TB burden country accounting for more than one- fifth of the global incidence

Estimated incidence 1.96 million new cases annually Over 1000 deaths a day , 2 deaths every 3 minutes

PATHOGENESIS M. tuberculosis produces no exotoxins and does not contain endotoxin in its cell wall. In fact, no mycobacteria produce toxins. M. tuberculosis can survive within inactivated macrophages. Because Activated macrophages can kill the bacteria. Individual's immunological response determines the outcome of exposure.Healthy individual who are exposed to low dose → activated macrophages stop infection. Individuals unable to mount a rapid response → bacteria multiply in lung macrophages. → phagocytes attracted to site of infection → infection may be walled-off/ forms tubercle. Tubercles may calcify and become visible in chest X-rays (Ghon complex)

GHON COMPLEX .

Macrophage engulfing M. tuberculosis pathogen.

Bacteria in tubercles may survive for decades (latency).

Suppression of immune system may allow bacteria to break out of lesions and multiply (reactivation). Old age, cancer, immunosuppressive drugs and HIV infection can lead to reactivation

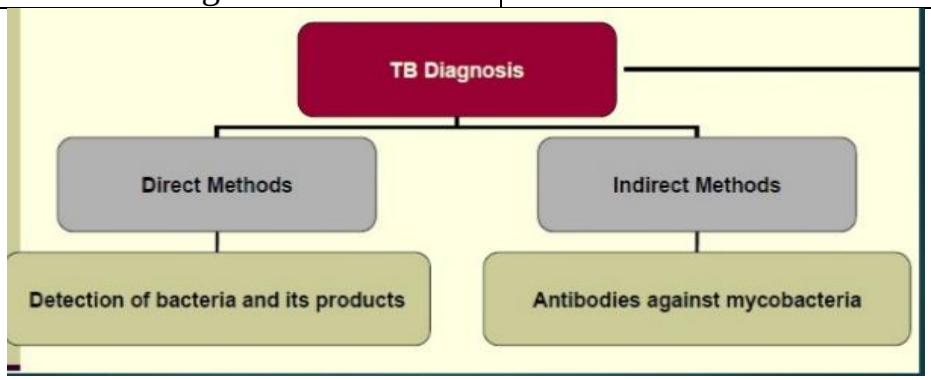
SIGNS AND SYPTOMS: During Active TB symptoms of TB are present, which can include: coughing , weight loss , loss of appetite , night sweats , fever , chest pain , Blood stained sputum.Active TB is infectious and can be spread by coughing, sneezing, laughing, singing, or just talking.

M. tuberculosis does not spread by: Sharing dishes and utensils Using towels and linens , Handling food. Sharing cell phones , Touching computer keyboard

LABORATORY DIAGNOSIS

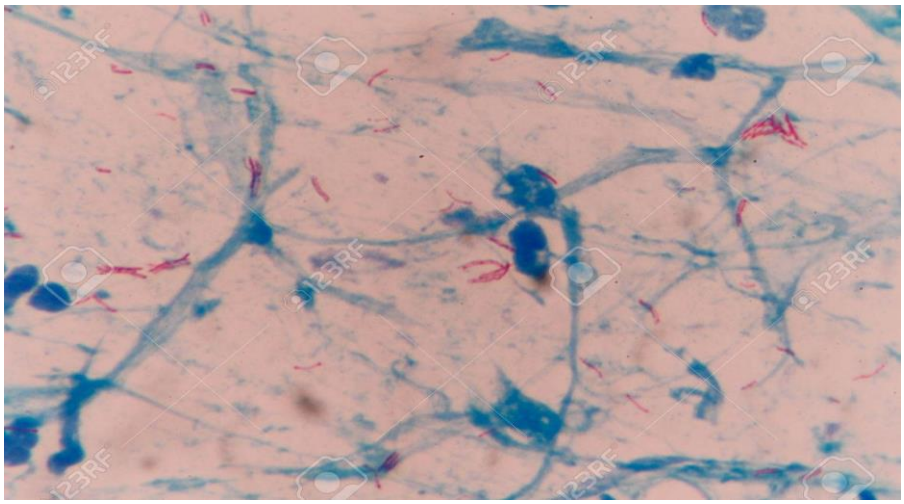
Specimen Collection :Early morning sputum samples should be collected for 3 consecutive days in a sterile container . In case of renal tuberculosis, 3-6 morning urine samples should be collected .

Type of lesion	Specimen
Pulmonary tuberculosis	Sputum
Renal tuberculosis	Urine
Tuberculous meningitis	CSF

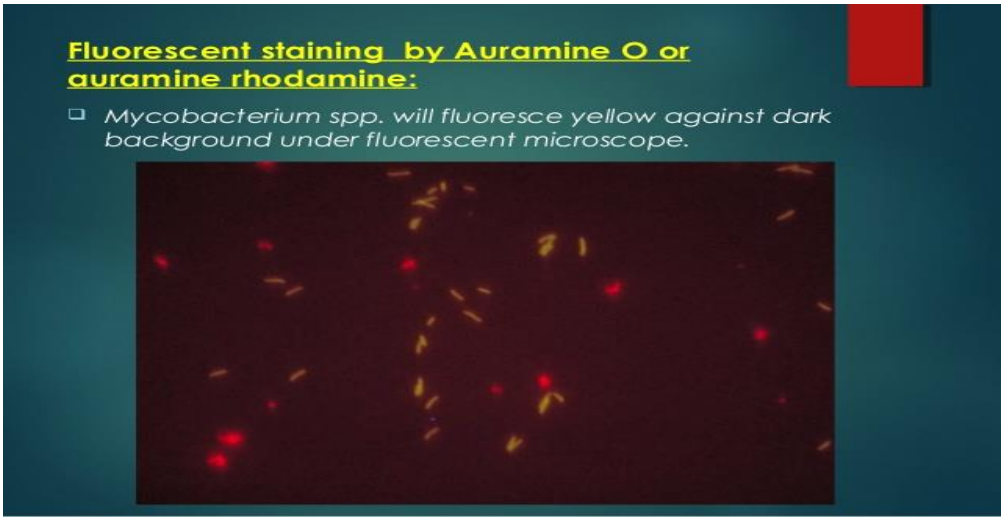


DIAGNOSTIC METHODS

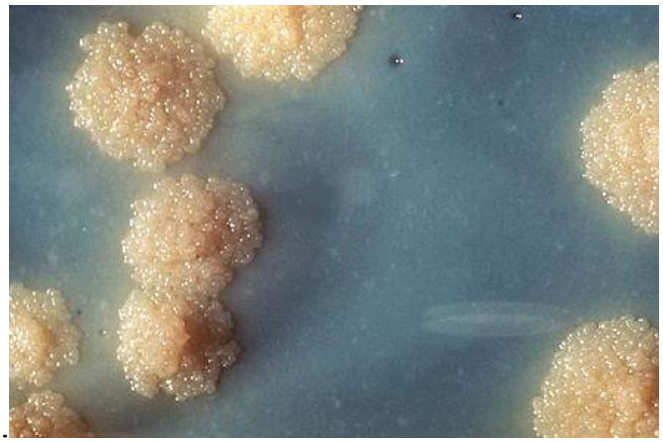
i) Direct Microscopy: Ziehl-Neelsen staining(hot staining method): With Ziehl-Nielsen stain, M. tuberculosis look slender, straight or slightly curved rod with beaded appearance.



Fluorescent staining by Auramine O or auramine rhodamine. Mycobacterium spp. will fluoresce yellow against dark background under fluorescent microscope.



ii) Culture: Concentrated specimen is generally inoculated on Lowenstein – Jensen's medium (solid medium) and incubated at 37^{o} C for 2 – 8 weeks. Lowenstein – Jensen's medium contains coagulated egg, Mineral salt solution, Asparagine's, Malachite green, Agar Colonies appear as buff coloured, dry, irregular colonies with wrinkled surface and not easily emulsifiable (Buff, rough and tough colonies). Colonies are creamy white to yellow colour with smooth surface.



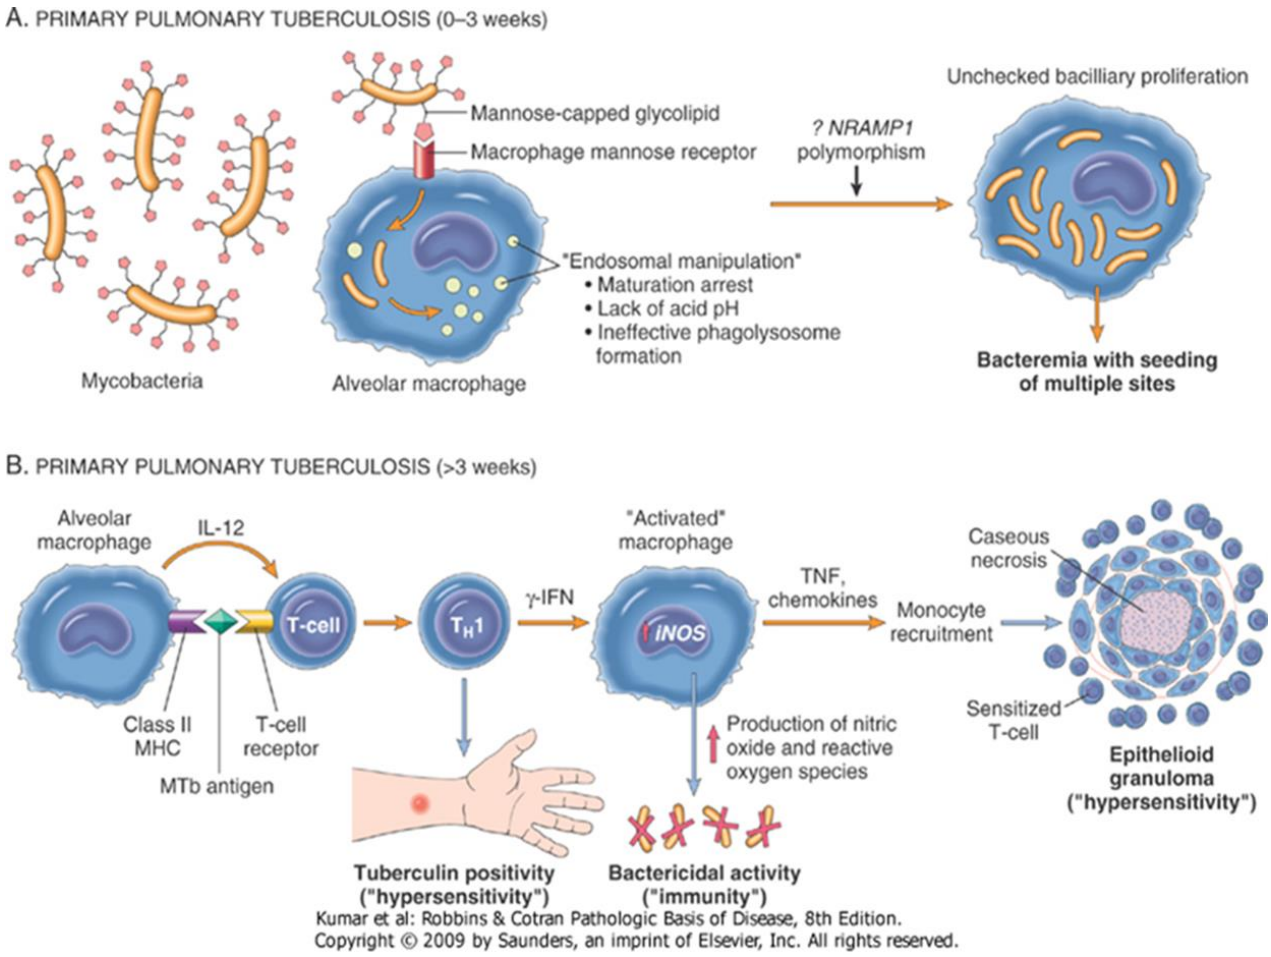
Colonies of Mycobacterium tuberculosis on Lowenstein-Jensen medium

iii) Allergic Test: Tuberculosis infection leads to the development of delayed hypersensitivity to *M. tuberculosis* antigen, which can be detected by Mantoux test. Mantoux test (tuberculin test) 0.5 ml of PPD (Purified Protein Derivative) is injected intradermally on flexor aspect of fore arm. Site is examined after 48 – 72 hrs

- Induration of 10 mm or more is considered positive. positive test leads to red area at injection site

Type 4 hypersensitivity is often called delayed type hypersensitivity as the reaction takes two to three days to develop. Unlike the other types, it is not antibody .mediated but rather is a type of cell-mediated response

CD4+ helper T cells recognize antigen in a complex with Class II major histocompatibility complex. The antigen-presenting cells in this case are macrophages that secrete IL-12, which stimulates the proliferation of further CD4+ Th1 cells. CD4+ T cells secrete IL-2 and interferon gamma, further inducing the release of other Th1 cytokines, thus mediating the immune response. Activated CD8+ T cells destroy target cells on contact, whereas activated macrophages produce hydrolytic enzymes and, on presentation with certain intracellular pathogens, transform into multinucleated giant cells



An example of a TB infection that came under control: *M. tuberculosis* are engulfed by macrophages after being identified as foreign, but due to an immuno-escape mechanism peculiar to mycobacteria, TB bacteria are able to block the fusion of their enclosing phagosome with lysosomes which would destroy the bacteria. Thereby TB can continue to replicate within macrophages. After several

weeks, the immune system somehow (mechanism as yet unexplained) ramps up and, on stimulation with IFN-gamma, the macrophages become capable of killing *M. tuberculosis* by forming phagolysosomes and nitric oxide radicals. However the hyper-activated macrophages secrete TNF which recruits multiple monocytes into the battle. These cells differentiate into epithelioid histiocytes which wall off the infected cells, but at the cost of significant inflammation and local damage

iv) Detection of Antibodies: Various methods such as enzyme linked immunosorbent assay (ELISA), radio immunoassay (RIA), latex agglutination assay have been employed for detection of antibodies in patient serum.

v) Biochemical Reactions: Niacin test: *M. tuberculosis* lacks the enzyme that converts Niacin to Niacin ribonucleotide due to this large amount of Niacin accumulates in the culture medium. Niacin is detected by addition of 10% cyanogen bromide and 4% aniline in 96% ethanol.

Positive reaction – canary yellow . *M. tuberculosis* – Positive . M. bovis - Negative

- Nitrate reduction test: M. tuberculosis produce an enzyme nitro reductase which reduces nitrate to nitrite. This detected by colorimetric reaction by addition of sulphanilamide and n-naphthyl- ethylene diamine dihydrochloride.

Positive reaction – pink or red colour *M. tuberculosis* – Positive . *M. bovis* – Negative

- *M. tuberculosis* is resistant to TCH (Thiophene - 2 - carboxylic acid hydrazide); hence, growth occurs. *M. bovis* is susceptible; therefore, does not grow.

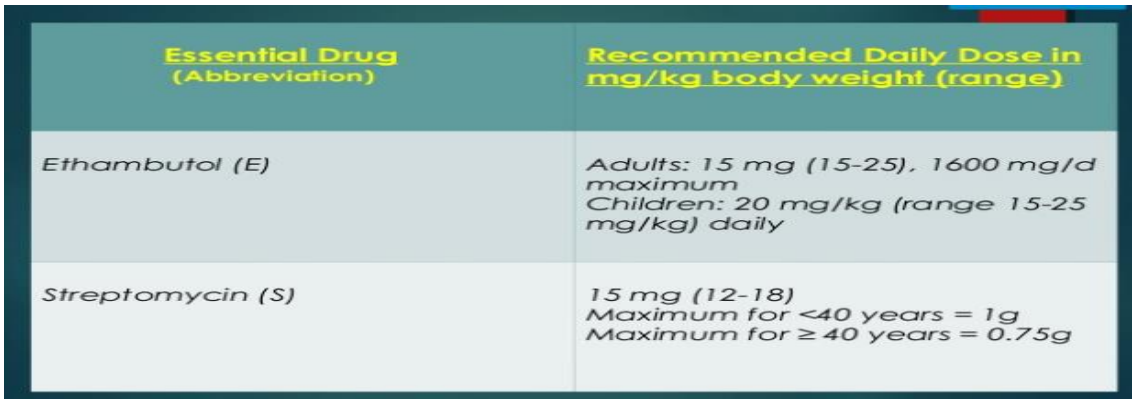
PROPHYLAXIS:

1. General measures: Adequate nutrition, good housing and health education are as important as specific antibacterial measures

2-Immunoprophylaxis: The BCG (Bacille Calmette-Guerin) vaccine (0.1 ml), administered soon after birth by intradermal Injection which may be given at any time during the first year of life. BCG is live attenuated strain derived from *M. bovis* → stimulates development of hypersensitivity to *M. tuberculosis*.

3-Chemoprophylaxis:

Essential Drug (Abbreviation)	Recommended Daily Dose in mg/kg body weight (range)
Isoniazid (H)	Adults: 5 mg (4-6) kg/d, 300mg/d maximum Children: 10-15 mg/kg/d, 300 mg/d maximum
Rifampicin (R)	Adults: 10 mg (8-12), 600mg/d maximum Children: 10-20 mg/kg/d, 600 mg/d maximum
Pyrazinamide (Z)	25 mg (20-30), 2000 mg/d maximum



Essential Drug (Abbreviation)	Recommended Daily Dose in mg/kg body weight (range)
Ethambutol (E)	Adults: 15 mg (15-25), 1600 mg/d maximum Children: 20 mg/kg (range 15-25 mg/kg) daily
Streptomycin (S)	15 mg (12-18) Maximum for <40 years = 1g Maximum for ≥ 40 years = 0.75g

other species such as *M. bovis*, *M. africanum* and *M. kansasii* can also cause disease. Infection is spread in droplets of sputum from patients with active pulmonary tuberculosis. In some patients infection also produces lesions within the oral cavity.The classical intra-oral presentation is of an ulcer on the dorsal surface of the tongue but lesions may
affect any site. The ulcers are irregular with raised borders and may resemble deep fungal infection or squamous cell carcinoma.A mucosal biopsy should be taken to demonstrate
the characteristic granulomatous inflammation with well-formed granulomata, Langhans giant cells and necrosis.
A Mantoux (tuberculin) skin test will be positive as a result of previous infection in patients who have not received prior BCG immunization. Oral lesions will resolve when systemic chemotherapy consisting of rifampicin, isoniazid, pyrazinamide and

ethambutol is administered. Typically, combinations of these drugs are given initially for 2 months after which time the therapy is reduced to isoniazid and rifampicin for a further 4 months. Longer and different regimens are required for the management of patients found to have resistant strains of *Mycobacterium tuberculosis*. Strains of *M. tuberculosis* that are resistant to the majority of the drugs that are used to treat this infection are referred to as multi-drug (MDR) or extensive (orextreme) drug resistant (XDR) strains. In the future,there may be difficulty in treating this condition.Vaccination with BCG is only partially effective in preventing TB.

Neisseria

Zainab kamil yousif

Medical microbiology

Third year

Neisseria

- Gram negative cocci bacteria constitute the largest group of human pathogens. triggers fever,inflammation,shock and intravascular coagulation(blood dissiminated clots within blood vessels).

- Almost every gram negative bacterium that can breach the skin or mucous membranes, grow at $37^{o}C$ and evade the immune system can cause disease and death in humans. Neisseria are fastidious organisms (do not survive long in the environment) gram negative.
Neisseria diplococci resemble coffee beans when viewed microscopically.
have capsules and pili,facultative anaerobies and oxidase positive.

- Of the 11 species of neisseria that colonize humans, only two are pathogens, N. gonorrhoeae and N. meningitidis . Most gonococcal infections are asymptomatic and self-resolving.

Biochemical identification

- All the medically significant species of *Neisseria* are positive for both catalase and oxidase. Different *Neisseria* species can be identified by the sets of sugars from which they will produce acid. For example, *N. gonorrhoeae* makes acid from only glucose, but *N. meningitidis* produces acid from both glucose and maltose.

Polysaccharide capsule:

- *N. meningitidis* has a polysaccharide capsule that surrounds the outer membrane of the bacterium and protects against soluble immune effector mechanisms within the serum. It is considered to be an essential virulence factor for the bacteria. *N.gonorrhoeae* possesses no such capsule.

Neisseria gonorrhoeae:

- *Neisseria gonorrhoeae*; commonly termed as gonococcus (gonococci in plural).
- In 1879, the gonococcus was first described by Neisser in gonorrheal pus.
- Members of the genus *Neisseria* dominate the mucous membranes of human and other animals.
- *Neisseria gonorrhoeae* is responsible to cause the sexually transmitted disease gonorrhoeae.
- Gonococci are suited to grow on mucous membranes and hence are not able to tolerate drying.

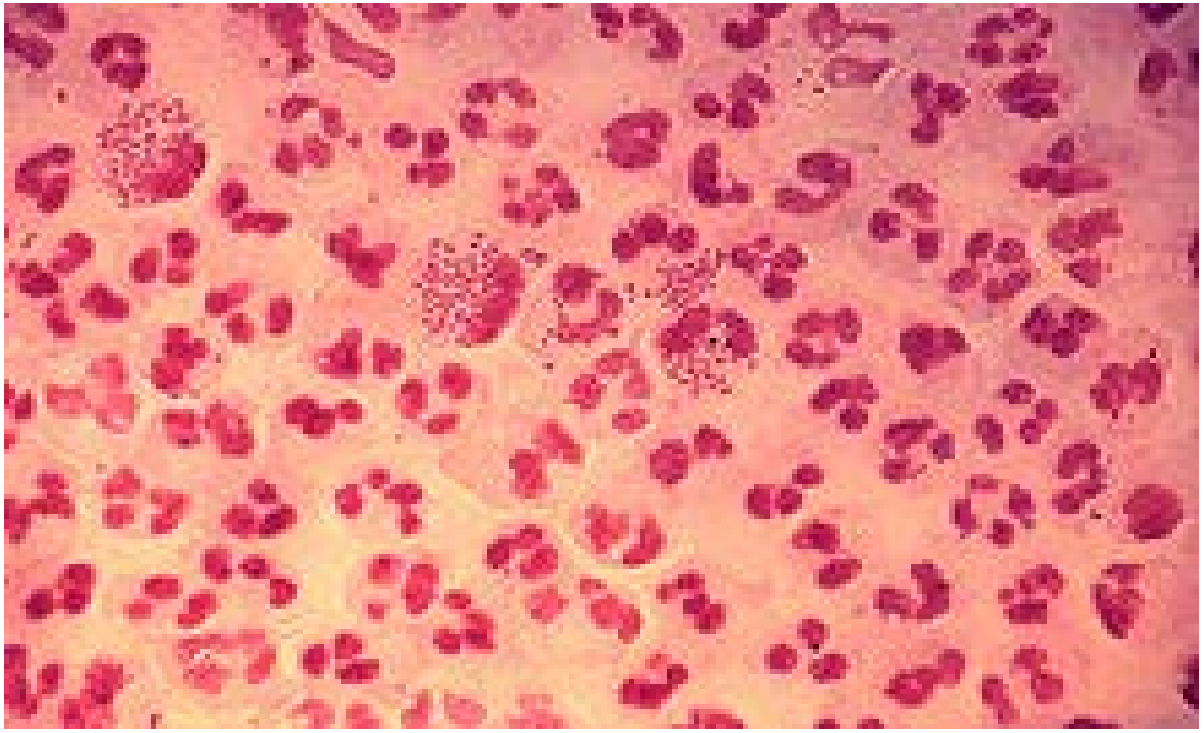
Their fragility restricts the transmission to direct contact between mucous membranes or the exchange of contaminated secretions .

•

Morphology of *Neisseria gonorrhoeae:*

- Under the microscope, it appears as a gram-negative coccus which is present in pairs (diplococci) with the flattening of the adjacent sides.
- The diameter ranges from 0.6-1 µm.
- The diplococci have kidney/coffee bean shape.
- It is a non-spore forming bacteria and is able to move using twitching motility.
- Gonococci exhibit pili on their surface.

Gram stain of N.gonorrhoeae



- Pili enhances the binding of the cocci to the mucosal surfaces and promotes virulence by restricting phagocytosis.
- Human red blood cells are agglutinated by piliated gonococci, but not red cells from other mammals.

- **Cultural and biochemical characteristics for identification of *Neisseria gonorrhoeae*:**

- Gonorrhoeae is a fragile organism with strict environmental and nutritional requirements.
- At pH 7.0-7.4 and at a temperature of 35-36 °C, growth occurs best.
- It is an aerobe meaning it needs oxygen to grow, however it can grow in anaerobic conditions as well.
- The supply of 5-10 percent CO_2 is needed.
- They grow rapidly on chocolate agar and Mueller-Hinton agar .The Thayer-Martin medium (chocolate agar

- containing antimicrobials such as vancomycin, colistin and nystatin) is a common selective medium that inhibits most contamination, including nonpathogenic Neisseria.
- Trimethoprim lactate may be introduced to the Thayer-Martin medium to suppress swarming Proteus species that are sometimes present in cervicovaginal and rectal specimens.

The growth of *Neisseria* colonies on chocolate agar

- *Neisseria gonorrhoeae* shows positive oxidase test (having cytochrome c oxidase) and is catalase positive as well, it can convert hydrogen peroxide to oxygen.
- The acid production takes place only from glucose and not from maltose, and also it does not ferment lactose or sucrose.

Oxidase test

Positive Negative

Oxidase test
Positive

Virulence factors of Neisseria gonorrhoae:

Pili: •

Pili are hair-like appendages that reach out of the gonococcal surface up to several micrometers. •

By facilitating attachment to host cells and inhibiting phagocytosis, they serve as virulence factors •

Por protein (Protein I): •

- The Por protein is an essential outer membrane protein present on all gonococcal strains.
- It forms pores or channels in the outer membrane.

Opa proteins (Protein II): •

- Opa are the opacity proteins that are variably expressed on gonnacoccal strains that is responsible for phenotypes of various colony.
- These proteins promote bacterial attachment to each other along with eukaryotic cells and also for the clumping of cocci seen in urethral exudate smears.

Rmp (Protein III): •

- Highly conserved Rmp proteins (reduction-modifiable proteins, formerly protein III) are the third group of proteins in the outer membrane.
- These proteins induce antibodies which inhibit the serum bactericidal activity against *N. gonorrhoeae.*

- **Lipo-oligosaccharide (LOS):**
  - This antigen has endotoxic activity and is composed of lipid A and a main oligo-saccharide identical to gram-negative lipopolysaccharide (LPS).
- **Other proteins:**
  - The other important gonococcal proteins are IgA protease which degrades secretory IgA and beta-lactamase which degrades penicillin.

Resistance showed by gonococcus:

- Gonococcus is a very sensitive organism, readily destroyed by drying, soap and water, and many other washing agents or antiseptic agents when used and diluted correctly.
- Organisms can remain viable in pus-contaminating linen or other fabrics for a day or so.
- In cultures, the coccus dies in 3-4 days at room temperature.
- The most effective method for long-term gonococcus storage is freeze-drying, but storage at-70 ° C or in liquid nitrogen might be more convenient for intermediate storage.

Pathogenesis of *Neisseria gonorrhoeae*:

Gonococcal Infection in men: •

- A few days after unprotected vaginal or anal sexual intercourse, acute urethritis in males is the most common clinical presentation.
- Discharge or dysuria normally occurs within 1 week of exposure, but there are never any signs or symptoms for as many as 5-10 percent of patients.
- The discharge is characteristically purulent, and in the gram stain of the exudate, gram-negative intracellular diplo-cocci can be easily seen.

- There may be an asymptomatic condition in men up to several weeks after infection.

Gonococcal infection in women: •

- The endocervix is the main site of infection in women and spreads to the urethra and vagina, causing mucopurulent discharge to occur.
- In adults, the vaginal mucosa is typically not affected because the stratified squamous epithelium is immune to cocci infection and also due to the acid pH of vaginal secretions, but in prepubertal girls, serious vulvovaginitis can occur.
- Asymptomatic carriage is prevalent in females, especially in the endocervical canal.

Vaginal discharge, dysuria, and abdominal pain are widely experienced by symptomatic patients.

- Clinical disease is less severe in women, many of whom may bear cervical gonococcus without any clinical symptoms.

Laboratory diagnosis of *Neisseria gonorrhoeae* :

- **Direct microscopy:**
- Gram staining is performed with a few extracellular species that are typical of gonococcal infection.
- The smear is confirmed showing characteristic kidney-shaped gram-negative diplococci lying inside polymorphonuclear leucocytes.

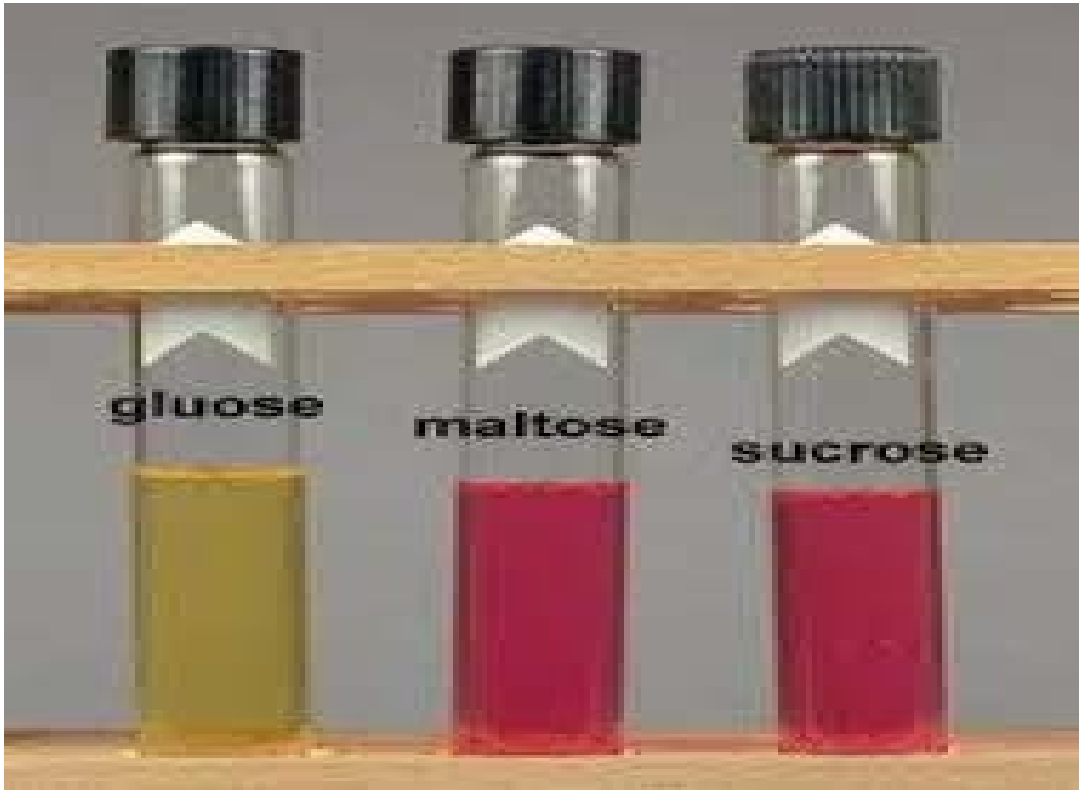
- **Culture:**
- In acute gonorrhea, cultures can be acquired commonly on chocolate agar or Mueller-Hinton agar incubated at 35-36°C along with 5-10% CO_2.
- However, it is best to use a selective medium such as the Thayer-Martin medium in chronic cases.

After 24 hours of incubation, the plates are examined and morphology and biochemical reactions identify the growth.

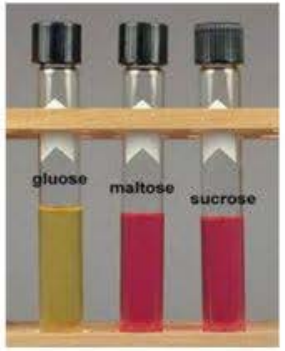
-

- **Biochemical reactions**
- Gonorrhoeae are preliminarily defined on the basis of the isolation of oxidase-positive.
- It only ferments glucose with acid.

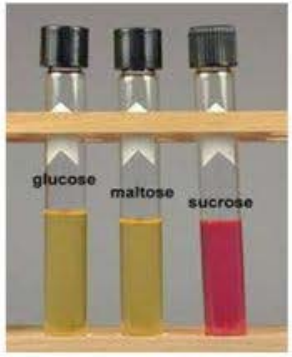
Neisseria gonorrhoeae test result



Neisseria spp. : Carbohydrate Utilization test



N. Gonorrhea



N. Meningitides

	Glucose	Maltose	Lactose
N. Gonorrhea	+	-	-
N. Meningitides	+	+	-

- **Serological diagnosis:**
- It is not really possible to obtain gonococci in culture from some chronic cases as well as from patients with metastatic lesions like arthritis.
- In such cases, serological tests are essential.
- Complement fixation tests
- Immunoblotting, radioimmunoassay, ELISA (enzyme-linked immunosorbent assay) tests.

- However, for routine diagnostic purposes, there was no serological test found to be useful.
- Such tests are neither sensitive nor precise and are not recommended for use.

Neisseria meningitidis

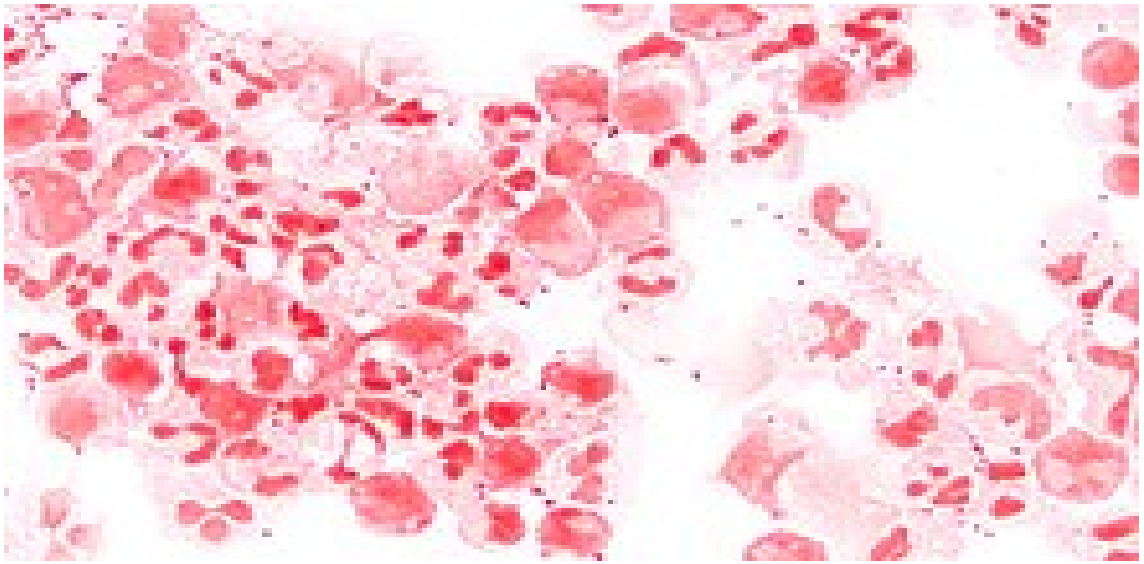
- ***Neisseria meningitidis***, often referred to as meningococcus, is a Gram-negative bacterium that can cause meningitis and other forms of meningococcal disease such as a life-threatening sepsis. The bacterium is referred to as a coccus because it is round, and more specifically, diplococcus because of its tendency to form pairs. About 10% of adults are carriers of the bacteria in their nasopharynx.

N. meningitidis is spread through saliva and respiratory secretions during coughing, sneezing, kissing, chewing on toys and even through sharing a source of fresh water.

-

Morphology

- *N. meningitidis* is a Gram-negative diplococcus since it has an outer and inner membranes with a thin layer of peptidoglycan in between. It is 0.6–1.0 micrometers in size. It tests positive for the enzyme cytochrome c oxidase.



Neisseria meningitidis **in cerebrospinal fluid (CSF) seen by Gram stain at 1000x magnification**

Diagnosis

- A small amount of cerebrospinal fluid (CSF) is sent to the laboratory as soon as possible for analysis. The diagnosis is suspected, when Gram-negative diplococci are seen on Gram stain of a centrifuged sample of CSF; sometimes they are located inside white blood cells. The microscopic identification takes around 1–2 hours after specimen arrival in the laboratory.

Biochemical tests : •

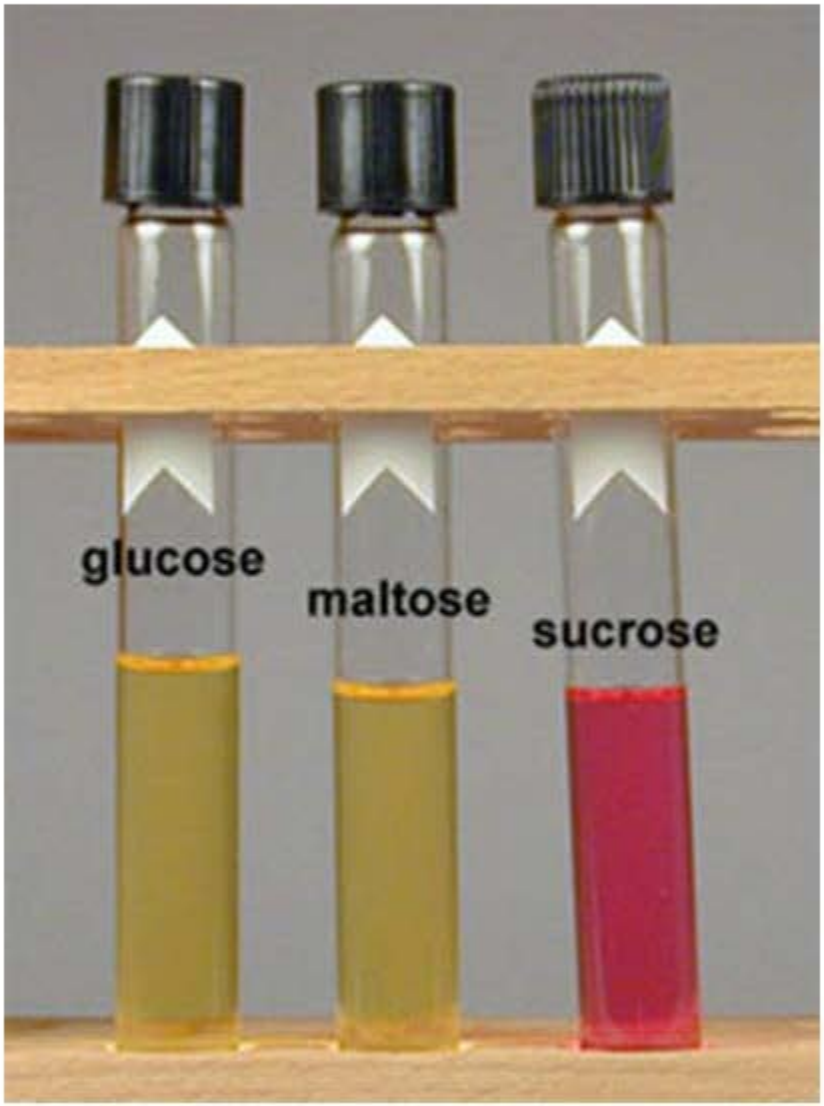
Oxidase positive •

Carbohydrate utilization test with CTA(Cystine trypticase agar)Sugars: •

It ferment glucose and maltose. •

Neisseria meningitidis

Carbohydrate Utilization



Virulence factors

- Lipooligosaccharide (LOS) is a component of the outer membrane of *N. meningitidis*. This acts as an endotoxin and is responsible for septic shock and hemorrhage due to the destruction of red blood cells. Other virulence factors include a polysaccharide capsule which prevents host phagocytosis and aids in evasion of the host immune response.

- Fimbriae mediate attachment of the bacterium to the epithelial cells of the nasopharynx.
- Meningococci produce an IgA protease, an enzyme that cleaves IgA class antibodies and thus allows the bacteria to evade a subclass of the humoral immune system.

Thank you •

Oral Normal flora

In a healthy human body, the internal tissues, e.g. blood, brain, muscle, etc., are normally free of microorganisms. However, the surface tissues are constantly in contact with environmental organisms and be colonized by various microbial species. The mixture of organisms regularly found at any anatomical site is referred to as the **normal flora**.

Normal flora is an aggregate of microorganisms that placed on the surface tissues which are constantly in contact with environmental atmosphere, i.e., skin and mucous membranes.

Oral Microbiota: The Normal bacterial flora that are placed in the oral cavity is called as oral microflora. Both host and bacteria are thought to derive benefit from each other, this the associations is, for the most part, **mutualistic.**

- This resident microflora contributes directly and indirectly to the normal development of the physiology, nutrition and defense systems of the host.
- The microbial colonization of all environmentally accessible surfaces of the body (both external and internal) begins at birth.
- Such surfaces are exposed to a wide range of microorganisms derived from the environment and from other persons For example, staphylococci and micrococci predominate on the skin surface.
- Similarly, over 700 types of microorganism found in the mouth are able to colonize the gastrointestinal tract, despite the continual passage of these microbes through the gut.

The relationship between the **Oral Microbiota** and the host can be broken down and the disease may occur. This usually because of:

1-Major biological changes of the mouth from exogenous sources (e.g. Antibiotic treatment) or **Endogenous changes** (Alterations in the host defenses) which affect the natural stability of the microflora.

2- -The presence of microorganisms at the sites not normally accessible to them as normal flora.

As a sequence of mouth-normal flora relationship disorder, an episodes of oral bacterial infections caused by its oral microflora. The commonest clinical aspect of such imbalances are dental caries and periodontal diseases.

Dental caries: is a decay of enamel or root surfaces by acid produced primarily from the metabolism of fermentable carbohydrates of the bacterial diet that are colonizing the tooth surface (dental plaque). Dental plaque is also associated with the etiology of periodontal diseases which causes an inappropriate inflammatory response to an increased microbial load (due to plaque accumulation) around the gingivae, resulting in damage to the supporting tissues of the teeth.

MICROBIAL ECOLOGY

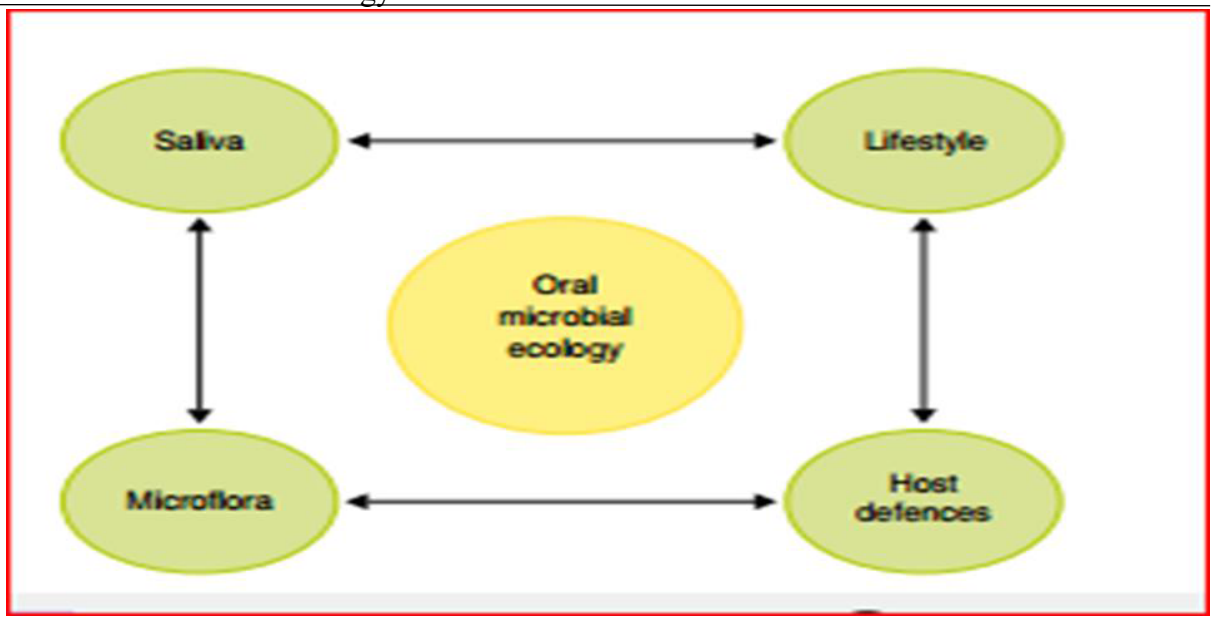
Most diseases of the mouth have a polymicrobial (multiple species) etiology. The ability of bacteria to cause disease depends on the outcome of various interactions among the microbes themselves, and between these microorganisms and the host. The composition and metabolism of bacteria at a site will be influenced by:

1- Flow rate and properties of saliva

2- The life-style of an individual (in particular, tobacco habit, the nature of the diet, and exposure to medication)

3- The integrity of the host defenses.

4- Oral microflora



The mouth as a microbial habitat

The properties of the mouth as a microbial habitat are dynamic, and will change during the life of an individual. During the first few months of life the mouth consists only of mucosal surfaces for microbial colonization. The eruption of teeth provides a unique, hard non-shedding surface which enables much larger masses of microorganisms (dental plaque) to accumulate as biofilms. When the Gingival crevicular fluid (GCF) is produced, it can provide additional nutrients for subgingival microorganisms. The ecology of the mouth will change over time due to the eruption or extraction of teeth, the insertion of orthodontic bands or dentures, and any dental treatment including scaling and restorations.

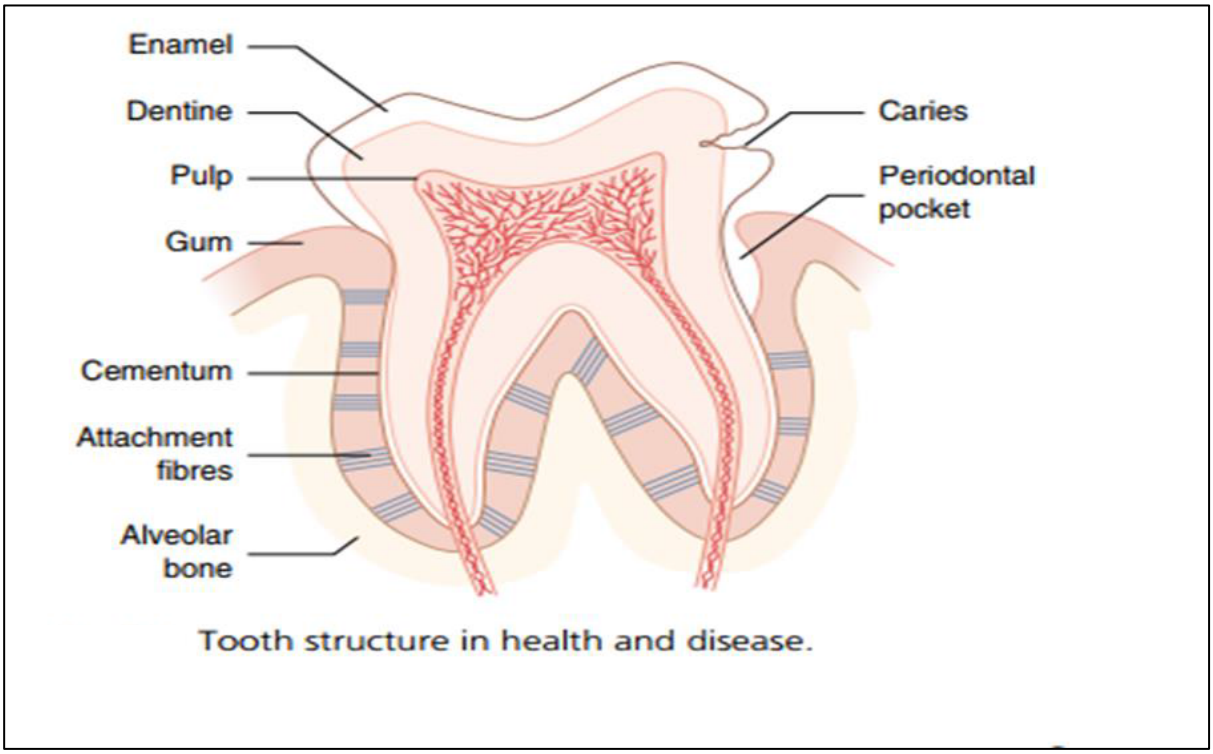
Transient fluctuations in the stability of the oral ecosystem may be induced by the frequency and type of food ingested, variations in saliva flow, and courses of antibiotic therapy.

Four features that help to make the oral cavity distinct from other areas of the body are: specialized mucosal surfaces, teeth, saliva and gingival crevicular fluid.

Mucosal surfaces

The mouth is similar to other ecosystems in the digestive tract in having mucosal surfaces for microbial colonization. The microbial load is relatively low on such surfaces due to desquamation. The papillary structure of the tongue dorsum provides refuge for many microorganisms which would otherwise be removed by mastication and the flow of saliva. Such sites on the tongue can also have a low redox potential which enable obligately anaerobic bacteria to grow and act as a reservoir for some of the Gram negative anaerobes that are implicated in the etiology of periodontal diseases and are responsible for malodor. The mouth also contains keratinized and non-keratinized stratified squamous epithelium which may influence the intra-oral distribution of some microorganisms.

Teeth : Teeth (and dentures) allow the accumulation of large masses of microorganisms and their extracellular products, termed dental plaque. In disease, there is a shift in the composition of the plaque microflora away from the species that predominate in health. With ageing, recession of the gingival tissues can expose cementum to microbial colonization and disease.



Tooth structure in health and disease.

Teeth do not provide a uniform habitat but possess several distinct surfaces. These surfaces are optimal for colonization and growth by different populations of microorganism.

_ The stagnant areas between adjacent teeth **(approximal)** and in the gingival crevice afford most protection to colonizing microorganisms in the mouth . Both sites are also anaerobic and, in addition, the gingival crevice region is bathed in the nutritionally-rich gingival crevicular fluid (GCF), particularly during inflammation.

_ **Smooth surfaces** are more exposed to the environment and can only be colonized by a limited number of bacterial species.

_Pits and fissures of the biting (occlusal) surfaces of the teeth also offer protection from oral removal forces such as saliva flow, and can contain impacted food debris. Environmental conditions on the tooth also vary in health and disease . For example, as caries progresses, the advancing front of the lesion penetrates the dentine. The nutritional sources can be changed and local conditions may become acidic and more anaerobic due to the accumulation of bacterial metabolism products. Similarly, in disease, the gingival crevice develops into a periodontal pocket and the production of GCF is increased. These new environments will select the microbial community most adapted to the prevailing conditions. change in the local environment possibly resulting in a shift in the composition and metabolism of the microflora.

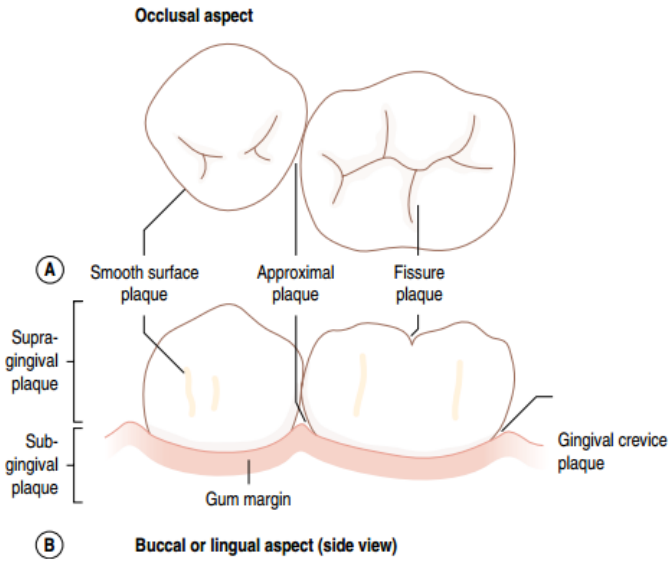


Diagram illustrating the different surfaces of a tooth, and the terminology used to describe dental plaque sampling sites.

Saliva

The mouth is kept moist and lubricated by saliva which flows to form a thin film (approximately 0.1mm deep) over all the internal surfaces of the oral cavity. Saliva plays major role in maintaining the integrity of teeth when dental plaque is produced, following the metabolism of dietary damaging acids (potentially carbohydrates). Bicarbonate is the major buffering system in saliva, but phosphates, peptides and proteins are also involved. The main pH of saliva is between pH 6.75 and 7.25, the pH and buffering capacity will vary with the flow rate. The slowest flow of saliva occurring during sleep.

The major organic constituents of saliva are **proteins and glycoproteins**, such as **mucin**, and they influence the oral microflora by:

• Adsorbing to the tooth surface to form a conditioning film (the acquired pellicle), when microorganisms are able to attach

• Acting as primary sources of nutrients (carbohydrates and proteins) for the resident microflora,

• Aggregating exogenous microorganisms, thereby facilitating their clearance from the mouth by swallowing,

• Inhibiting the growth of some exogenous microorganisms.

Other **nitrogenous** compounds provided by saliva include urea and numerous amino acids. The concentration of free carbohydrates is low in saliva, and most oral bacteria produce glycosidases to degrade the side-chains of host glycoproteins.

Antimicrobial factors, including lysozyme, lactoferrin, and the sialoperoxidase system, are present in saliva and play a key role in controlling bacterial and fungal colonization of the mouth. Antibodies have been detected, with **secretory IgA (sIgA) being the predominant class of immunoglobulin; IgG and IgM are also present but in lower concentrations**. A range of peptides with antimicrobial activity, including histidine-rich polypeptides (histatins), cystatins and defensins are also present in saliva.

Gingival crevicular fluid (GCF)

Serum components can reach the mouth by the flow of a serum-like fluid through the junctional epithelium of the gingiva. The flow of gingival crevicular fluid (GCF) is relatively slow at healthy sites, increases in gingivitis and in advanced periodontal diseases, as part of the inflammatory response to the accumulation of plaque around the gingival margin.

GCF can influence the microbial ecology of the site in a number of ways.* Its flow will remove non-adherent microbial cells, and *introduce components of the host defenses, especially IgG and neutrophils.

GCF is a source of nutrients for the resident microorganisms . Many bacteria from subgingival plaque are proteolytic and interact synergistically to break down the host proteins and glycoproteins to provide peptides, amino acids and carbohydrates for growth. Essential cofactors for growth, including haemin for black-pigmented anaerobes, from the degradation of haeme-containing molecules such as transferrin, haemopexin, and haemoglobin. The increased production of gingival crevicular fluid during diseases leads to decrease of the

periodontal pocket acidity (pH during health is 6.90, while pH during periodontal diseases is between 7.25 - 7.75). proteases of opportunistic pathogens is enhanced at alkaline pH (pH 7.5–8.0).

GCF contains components of the host defenses. regulating the microflora of the gingival crevice in health and disease. **IgM and IgA are also present, as acomplement.** GCF contains leukocytes, of which 95% are neutrophils (can phagocytose bacteria within the crevice), the remainder being lymphocytes and monocytes

.

Factors Affecting Oral Microbial Growth

Temperature

The human mouth temperature is (35–36°C) provides stable conditions, suitable for the growth of microorganisms. Periodontal pockets with inflammation have a higher temperature (up to 39°C) compared with healthy sites. Small increasing in temperature can significantly alter bacterial gene expression, and possibly the competitiveness of individual species. A rise in temperature down-regulates the expression of some of the major proteases and fimbriae proteins in the periodontal pathogen, *Porphyromonas gingivalis*, and up-regulates synthesis of superoxide dismutase, which is involved in the neutralization of toxic oxygen metabolites.

Oxygen tension :

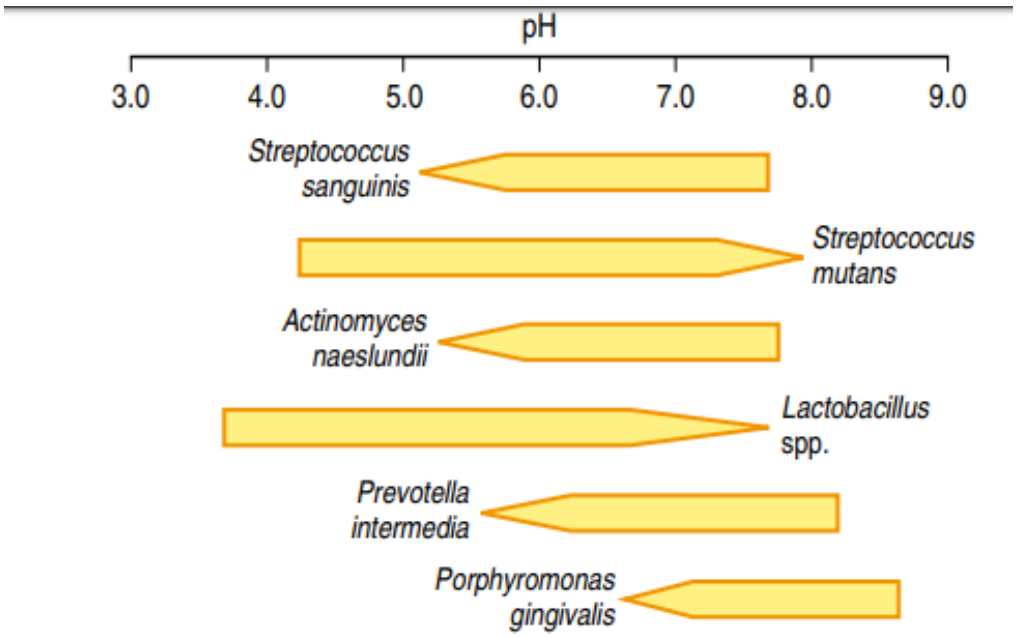
Oxygen concentrations are very at different locations in the oral cavity.

As may be expected, the dorsum of the tongue and the buccal and palatal mucosa are in an essentially aerobic environment.

The oxygen tension inside a periodontal pocket is very low, with the species having a tendency to become reduced rather than oxidized, explaining the survival of obligate anaerobe. Therefore obligate aerobic organisms (which

require oxygen) cannot survive, whereas obligate anaerobic organisms (which cannot tolerate the presence of oxygen) are able to thrive.

pH : Shifts in the proportions of bacteria within dental plaque can occur following fluctuations in environmental pH . After sugar consumption, the pH in plaque can fall rapidly to below pH 5.0 by the production of lactic acid, the bacteria in plaque will be exposed to varying challenges of low pH . Many of the bacteria that are associated with healthy sites can tolerate brief conditions of low pH, but are inhibited or killed by frequent or long exposures to acidic conditions. This can enhanced growth of, or colonization by, **acid-tolerant species, mutans streptococci and Lactobacillus** .In contrast, the pH of the gingival crevice can become alkaline during the host inflammatory response in periodontal disease, probably as a result of bacterial metabolism, e.g. ammonia production from urea. The pH of the healthy gingival crevice is 6.90, and rises to between pH 7.2 and 7.4 during disease. High PH can alter the pattern of gene expression in subgingival bacteria



A diagrammatic representation of the pH range for growth of some oral bacterial species.

Nutrients:

(i) Endogenous nutrients The persistence and diversity of the resident oral microflora is due primarily to the metabolism of the endogenous nutrients provided by the host, rather than by exogenous factors in the diet.

Saliva, which contains amino acids, peptides, proteins and glycoproteins vitamins and gases.

Gingival crevice is supplied with GCF(nutrients, such as albumin and other host proteins and glycoproteins, including haeme containing molecules) .

(ii) Exogenous (dietary) nutrients ,fermentable carbohydrates are the only class of compound that markedly influence the ecology of the mouth. broken down to acids.

The levels of acid-tolerating species, especially mutans streptococci and lactobacilli, increase while the growth of acid-sensitive species is inhibited or decreased. This predispose a site to dental caries. Dairy products (milk, cheese) have some influence on the ecology of the mouth.

Host defenses

Mucosa (and enamel) a physical barrier to prevent penetration by microorganisms or antigens

(i) Innate immunity: Chewing and the natural flow of saliva (or GCF in the gingival crevice) will remove microorganisms not firmly attached to an oral surface, and their physical removal by **swallowing** is an important defense mechanism., desquamation ensures that the bacterial load on most mucosal surfaces is light

Mucins agglutinate oral bacteria, interact with exogenous pathogens such as *Staphylococcus aureus* and *Pseudomonas aeruginosa*, as well as viruses including influenza virus.

Lysozyme aggregate both Gram positive bacteria (including streptococci) and Gram negative periodontal pathogens. lyse bacteria by hydrolyzing peptidoglycan.

Chitinase attacking yeast cell walls.

lactoferrin bactericidal to a range of Gram positive and Gram negative bacteria and anti-inflammatory

Defensins are a family of antibacterial peptides with a broad spectrum of antibacterial, antifungal and antiviral (including HIV) activity.

Cathelicidin antimicrobial peptide that is secreted by epithelial cell.

(ii) Adaptive immunity: Components of the specific host defenses (intraepithelial lymphocytes and Langerhans cells, immunoglobulins IgG and IgA) are found on and within the mucosa .where they act as a barrier to penetrating antigens. The predominant immunoglobulin in the healthy mouth is secretory IgA (sIgA), which is produced by plasma cells in the salivary gland. sIgA can agglutinate oral bacteria, modulate enzyme activity, and inhibit the adherence of bacteria to the buccal epithelium and to enamel. sIgA is usually

considered to be a first line of defense compared with other classes of immunoglobulin.

The resident oral microflora

Gram positive bacteria are commonly distributed on most surfaces of the mouth. The predominant genera are **Streptococcus and Actinomyces**; representative species are found at healthy sites, although many can also act as opportunistic pathogens. For example, **mutans streptococci** are implicated in dental caries .

GRAM POSITIVE COCCI

Streptococcus : Streptococci have been isolated from all sites in the mouth and comprise a large proportion of the resident oral microflora.

S. mutans ,S. salivarius and S. vestibularis , S. milleri , S. sanguis

Other Gram positive cocci : *Enterococcus faecalis*

GRAM POSITIVE RODS AND FILAMENTS

Eubacterium and related genera : *Eubacterium saburreum, E. yurii*. Mogibacterium

Lactobacillus: The most common species are

L. casei, L. rhamnosus, L. fermentum, L. acidophilus, L. salivarius, L. plantarum, L. paracasei, L. gasseri and L. oris.

Other genera : Corynebacterium

Oral Gram negative bacteria are diverse, and include species that are facultatively and obligately anaerobic, as well as species that are microaerophilic and capnophilic. **Veillonella** are anaerobic Gram negative cocci that play an important role in dental plaque by converting lactate to weaker acids. Most of the anaerobic Gram negative bacilli are found in dental plaque, and have an

asaccharolytic metabolism, and depend on proteins and glycoproteins for their nutrition; some common genera include Prevotella and Fusobacterium.

GRAM NEGATIVE COCCI: Neisseria**,**Veillonella **,**

Facultatively anaerobic and capnophilic genera

H. parainfluenzae

Obligately anaerobic genera : Prevotella

FUNGI Aspergillus, Candida(*Candida albicans*)

VIRUSES: Cytomegalovirus

PROTOZOA: *Trichomonas tenax, Entamoeba gingivalis*

Oral flora changes with age

Time during a lifetime	MAJOR COMPONENTS & CHANGES IN ORAL FLORA
Newborn	Oral cavity sterile. Soon colonised by facultative and aerobic organisms; esp *S. salivarius*
6 months	Flora becomes more complex & includes anaerobic orgs eg. *Veillonella sp. & Fusobacteria*
Tooth eruption	Increase in complexity. *S sanguis, S mutans* and *A viscosus* appear. New habitats include hard surfaces and gingival crevice.
Child to adult	Various anaerobes frequently found inc. Members of the *Bacteroidaceae. Spirochaetes* isolated more frequently
Loss of teeth	Disappearance of *S mutan, S sanguis, spirochaetes* and many anaerobes
Dentures etc	Reappearance of bacteria able to grow on hard surfaces

Fungal cells

Fungal cells are of two basic morphological types: true hyphae (multicellular filamentous fungi) or the yeasts (unicellular fungi), which make pseudohyphae. A fungal cell has a true nucleus, internal cell structures, and a cell wall. The main types of 'cells' produced by human pathogenic fungi are hyphae, yeast cells, and spores.

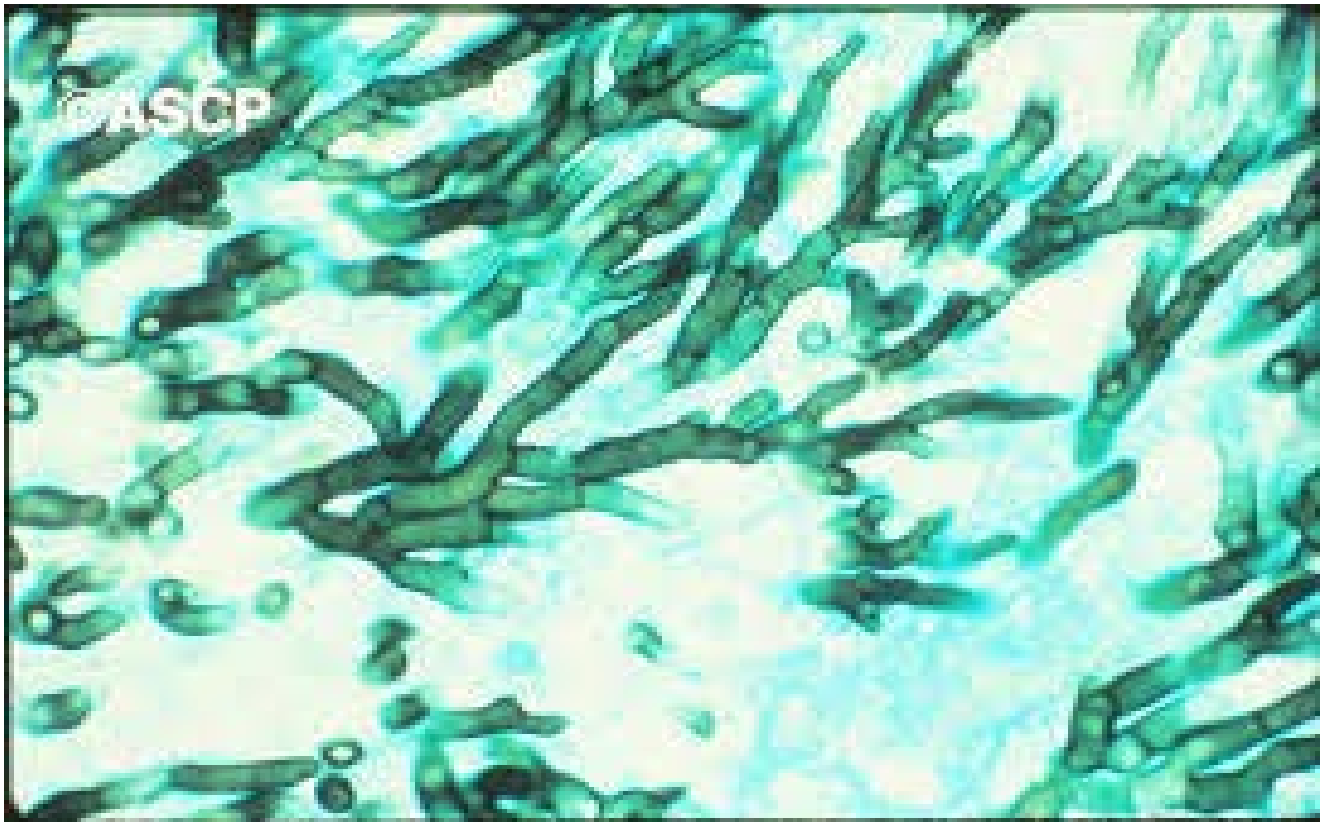
- Furthermore, hyphae may have some specialized structure or appearance that aids in identification.

Morphological types of fungi :

Three major groups :

1. Molds(filamentous)fungi.
2. Yeasts fungi.
3. Dimorphic fungi : fungi that have both a yeast stage and a mold stage , Mushrooms.

Filamentous fungi



Fungi Groups

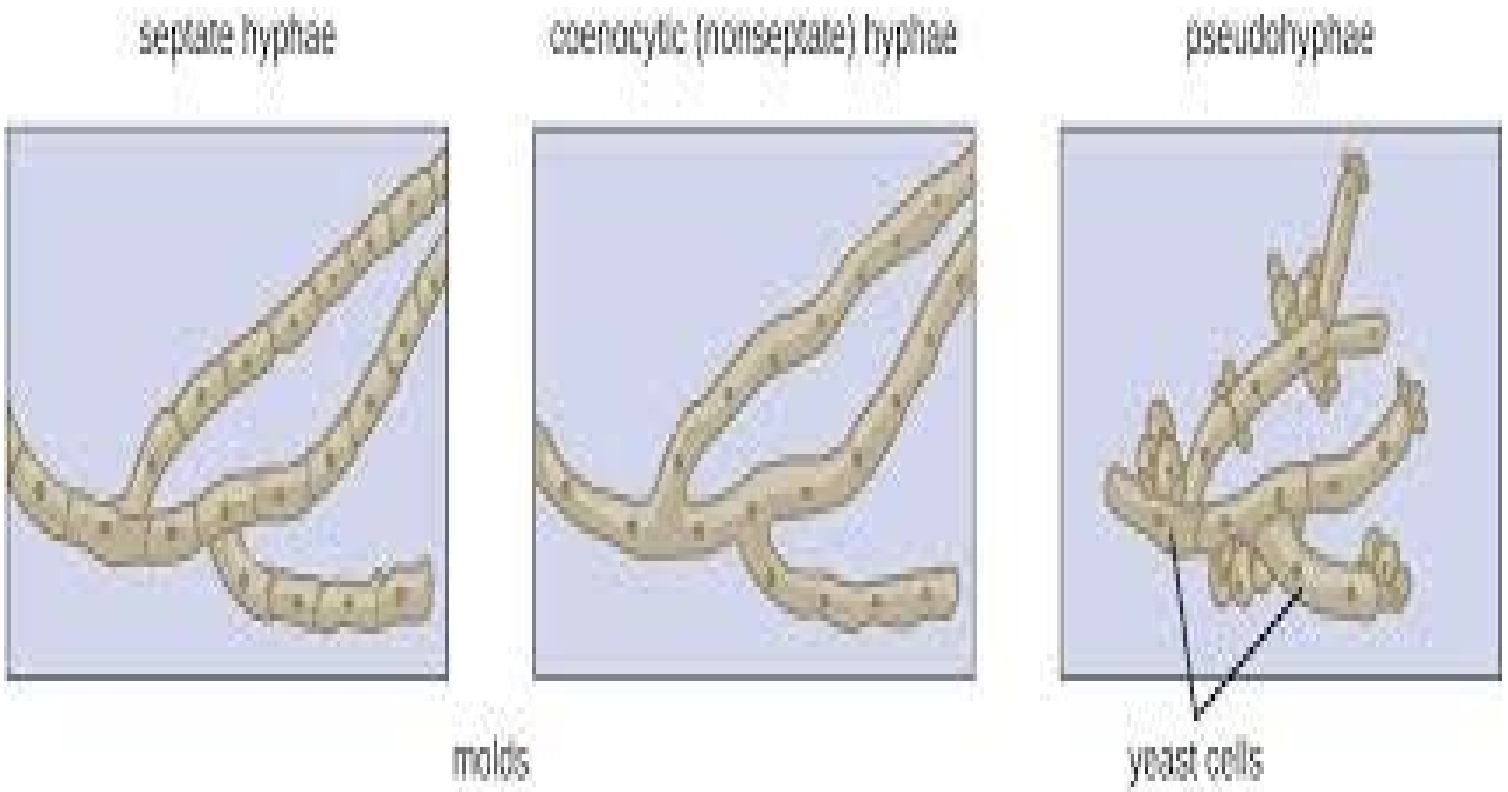
On the basis of Morphology

1. Molds (filamentous fungi)

- Most fungi are composed of filamentous (tubular) structures called hyphae. May be septated OR Aseptated

Aseptate hyphae

Septate hyphae



septate hyphae
coenocytic (nonseptate) hyphae
pseudohyphae
molds
yeast cells

Reproduction

- The simplest method of reproduction of fungi is by fragmentation of the thallus, the body of a fungus. Some yeasts, which are single-celled fungi, reproduce by simple cell division, or fission, in which one cell undergoes nuclear division and splits into two daughter cells; after some growth, these cells divide, and eventually a population of cells forms. In filamentous fungi the mycelium may fragment into a number of segments, each of which is capable of growing into a new individual.

- Budding, which is another method of asexual reproduction, occurs in most yeasts and in some filamentous fungi. In this process, a bud develops on the surface of either the yeast cell or the hypha, with the cytoplasm of the bud being continuous with that of the parent cell. The nucleus of the parent cell then divides; one of the daughter nuclei migrates into the bud, and the other remains in the parent cell. The parent cell is capable of producing many buds over its surface by continuous synthesis of cytoplasm and repeated nuclear divisions.

- After a bud develops to a certain point and even before it is severed from the parent cell, it is itself capable of budding by the same process. In this way, a chain of cells may be produced. Eventually, the individual buds pinch off the parent cell and become individual yeast cells. Buds that are pinched off a hypha of a filamentous fungus behave as spores; that is, they germinate, each giving rise to a structure called a germ tube, which develops into a new hypha.

- Sexual reproduction, an important source of genetic variability, allows the fungus to adapt to new environments. The process of sexual reproduction among the fungi is in many ways unique. In fungi the nuclear membrane remains intact throughout the process, although gaps in its integrity are found in some species.
The nucleus of the fungus becomes pinched at its midpoint, and the diploid chromosomes are pulled apart by spindle fibres formed within the intact nucleus. The nucleolus is usually also retained and divided between the daughter cells, although it may be expelled from the nucleus, or it may be dispersed within the nucleus but detectable.

Hyphae: •

- The majority of fungi are moulds, which are characterized by producing filamentous hyphae. Different types of hyphae possess unique combinations of structural, behavioural, and functional attributes.

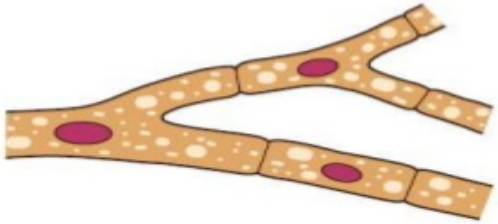
- The vegetative hypha at the periphery of a colony is a tip-growing cellular element that undergoes regular branching, is commonly multinucleate, and usually produces septa (cross walls). The mass of vegetative hyphae in the colony of a filamentous fungus is referred to as a mycelium. Many (but not all) filamentous fungi undergo prolific cell fusion within the colony to form a complex interconnected hyphal network.

Yeast cells •

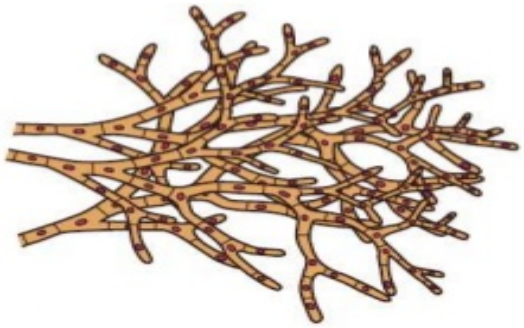
- Yeast cells are typically uninucleate single cells that reproduce vegetatively by processes involving septation and separation of daughter cells that can occur either by budding or by binary fission. The budding yeast *Saccharomyces cerevisiae* and the fission yeast, *Schizosaccharomyces pombe,* have been studied extensively as eukaryotic models, particularly in relation to the cell cycle and cell polarization.

Yeasts

There are two basic morphological forms: hypha & yeast



a Hypha, septate, or nonseptate



b Mycelium: web of branched hyphae

c Yeast form, budding

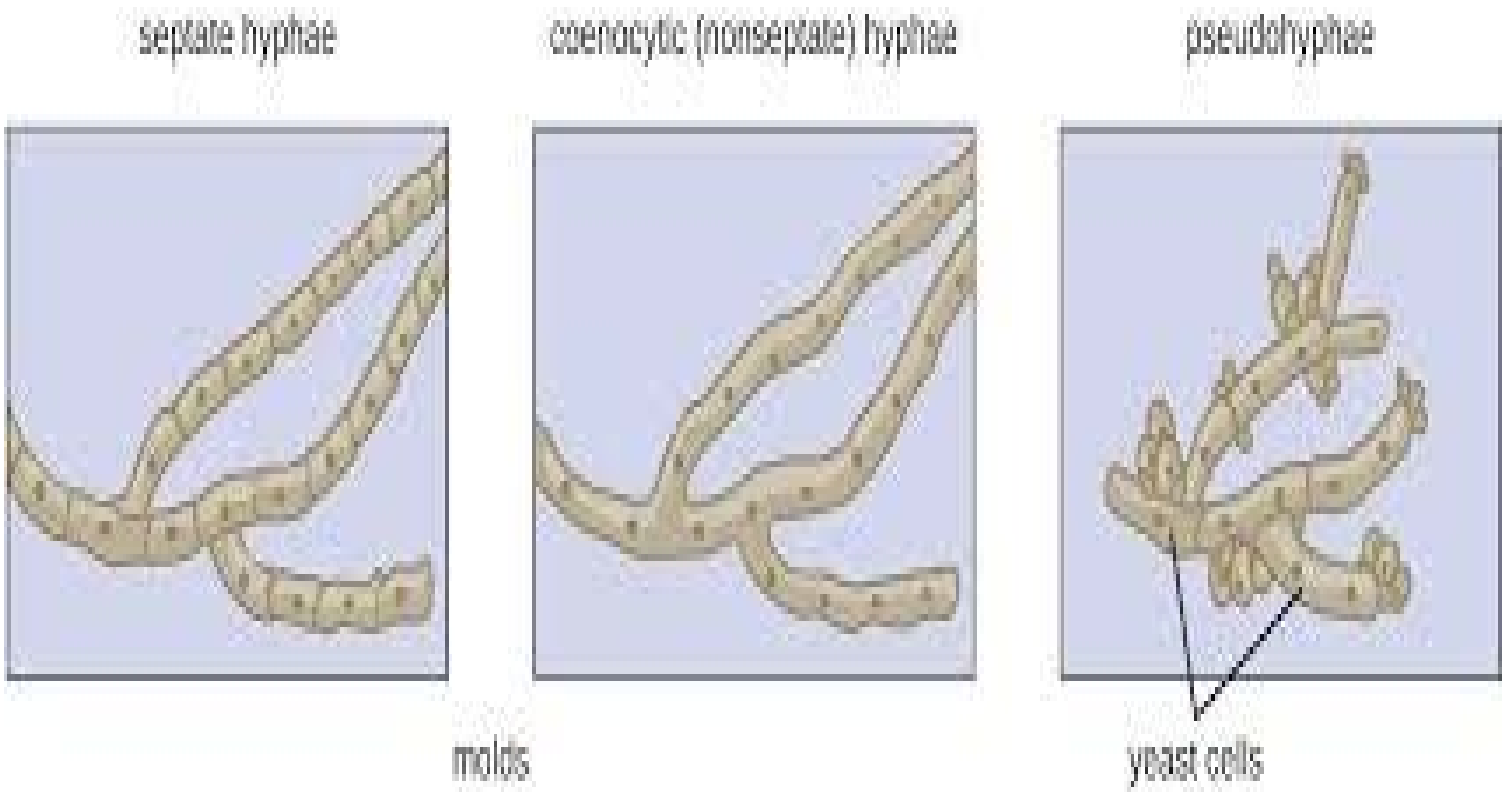
d Pseudomycelium

Basic Morphological Elements of Fungi

- Many important fungal pathogens produce yeast cells, and most of these (e.g. *Candida, Cryptococcus, Histoplasma, Blastomyces*, and *Paracoccidioides*) propagate themselves during infection by budding with the notable exception of the yeast cells of *Penicillium* (*Talaromyces) marneffei*, which reproduce by binary fission. Besides producing yeast cells, most of these pathogens are described as *dimorphic* or filamentous yeasts because, under certain conditions, they can produce hyphae . Indeed, some species (notably *C. albicans*) are often called *polymorphic* because they also form *pseudohyphae*, which more closely resemble yeast cells than hyphae.

Pseudohyphae •

These are formed by budding yeast cells • remaining attached and becoming elongated. Subsequent budding of these attached cells results in highly branched structures with constrictions between each cell. Mechanical agitation easily disrupts the attachment between pseudohyphal cells.



septate hyphae
coenocytic (nonseptate) hyphae
pseudohyphae
molds
yeast cells

Dimorphism •

The ability to exhibit dimorphic switching • between a yeast and a hyphal growth form is a key feature of many human fungal pathogens. In *C. albicans*, both morphological forms, as well as pseudohyphae, are important for virulence and have distinct functions during the different stages of disease development, including adhesion, invasion, damage, dissemination, immune evasion, and the host response.

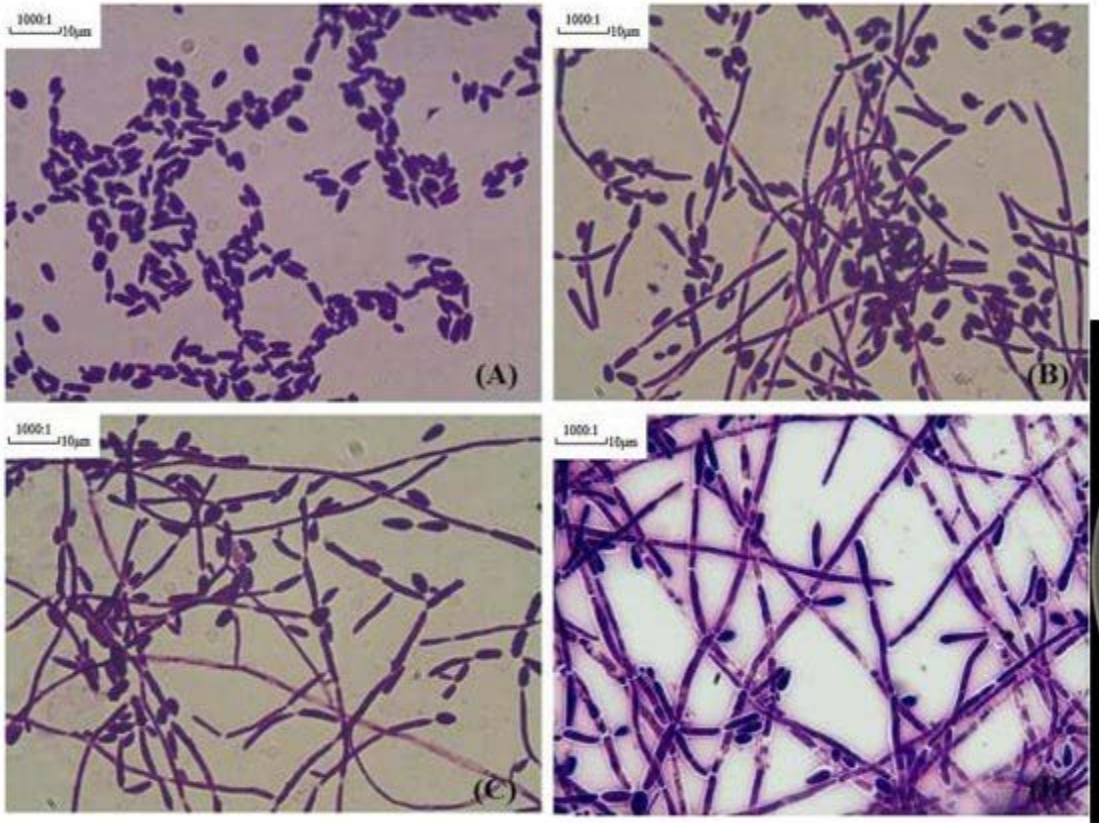
Oral Aspect of fungal infections

Fungal infections in the oral and perioral regions occur either as primary localized lesions or as manifestations of systemic mycoses. The most common group of fungal infections that dental practitioners diagnose and treat are caused by Candida spp. Some of the rarer mycoses such as histoplasmosis .

-

- The majority of opportunistic oral mucosal fungal infections are due to *Candida albicans* and *Aspergillus fumigatus* species. *Mucor* and *Cryptococcus* also have a major role in causing oral infections, whereas,*Fusarium*,*Saccharomyces* and *Penicillium marneffei* are uncommon pathogens in the oral cavity. The broad spectrum of clinical presentation includes pseudo-membranes, abscesses, ulcers, pustules and extensive tissue necrosis involving bone.

- Yeasts occur commonly in the oral cavity in healthy individuals. The prevalent species is Candida albicans (about 60-70% of all isolates) and C. tropicalis. The yeast flora increases in many patient groups, especially those who are immunocompromised.
- **C. albicans** is the most important species, being the cause of almost all cases of yeast infections in the region, often in association with other species. The number isolated from the oral cavity depends on testing site and methods used.



Candida tropicalis

Other species responsible for oral infections have also been identified including C. glabrata, C. krusei, C. parapsilosis, and C. tropicalis.

-

Candidiasis

- Is a primary or secondary mycotic infection caused by members of the genus Candida , the clinical manifestations may be acute, sub- acute or chronic and involvement may be localized to the mouth, throat, skin, scalp, vagina, fingers, nails, bronchi, lungs, or the gastrointestinal tract, or become systemic as in septicemia, endocarditic and meningitis .Systemic candidiasis is usually seen in patients with cell-mediated immune deficiency, and those receiving aggressive cancer treatment, immunosuppression, or transplantation therapy.

Oral candidiasis

Thrush •

It is an infection of mouth caused by Candida and the common sign of thrush is the presence of creamy white , slightly raised lesion of the mouth . The lesion , may have a "cottage cheese " appearance , in severe cases , may spread into the esophagus, causing pain or difficulty swallowing .

Stomatitis

Stomatitis is an inflammation of the mucus lining of any of the structures in the mouth which may involve the gums , tongue , lips and throat .

Erythematous candidosis

- Related to dentures is the most common form of oral candidosis in about 50 % of denture wearer.

Oral thrush

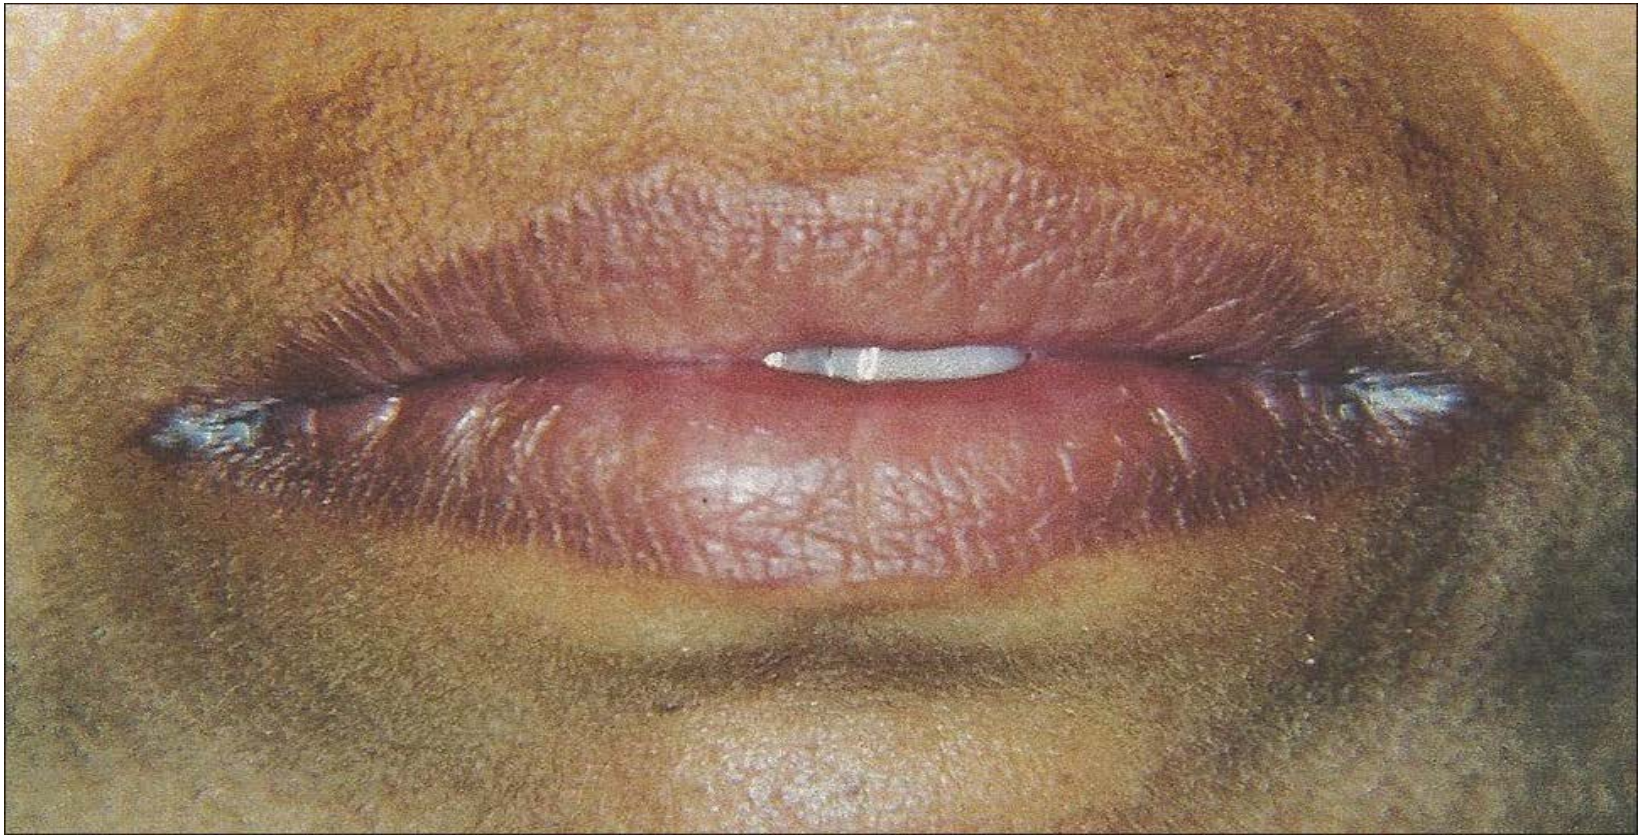
Candida-associated denture stomatitis

Candidiasis

Angualr cheilitis •

Angular cheilitis is an inflammatory lesion at the corner of the mouth and often occurs bilaterally. Nutritional deficiencies such as vitamin B12 and iron also some underlying causes for angular cheilitis . It also reported that angular cheilitis is one of the common presentations of oral candidiasis in HIV infected patients.

Angular cheilitis



Pathogenesis •

The ability of Candida to adhere to the mucosa and dentures plays an important role in the pathogenesis of oral yeast infections . Adherence is achieved by specific and nonspecific mechanisms. However the mechanisms of are still not fully understood . Local defense mechanisms have a key role in preventing yeast colonization in the oral cavity.

- These include the physical local barrier of the epithelia, secretory immunoglobulin A, and salivary factors such as flow rate and specific molecules (lysozyme, histatin and lactoferrin). Secreted aspartic proteinase (SAP), phospholipases and lipases are extracellular enzymes that facilitate adherence and/or tissue penetration. SAPs efficiently degrade extracellular matrix and host surface proteins (laminin, fibronectin, and mucin).

Histopathology •

The histological profile of C. albicans infections shows yeasts and pseudohyphae. C. glabrata, however, appears to produce only yeast forms . Histopathologic response is in most cases characterized as inflammatory or as an abscess.

Examples risk patients for oral candidiasis

- Patients with dental prosthese
- Patients with reduced salivary flow rate
- Patients with oral mucosal diseases
- Asthmatic patients on corticosteroid therapy
- Diabetic patients
- Patients with rheumatic diseases
- HIV infected and AIDS patients
- Patients with malignant disease
- Patients receiving immunosuppressive drugs
- Patients receiving radiotherapy to the head and neck
- The elderly.

Identification of Candida

- Microscopic examination of the smears stained KOH preparation can reveal candidal hyphae and blastospores.
- Culture on Sabouraud's dextrose agar (SDA) at 25-30^{o}C for 48-72 hours.Germ tube growth can be used for identification of *C. albicans*.

- CHROM agar is a medium that is widely used to identify C. albicans, C. krusei, and C..tropicalis. The medium contains chromogenic substrates which react with enzymes secreted by the target micro-organisms to yeald colonies of varying colours. C.albicans forms green colonies, C.tropicalis steel blue colonies, and C.krusei forms rose coloured colonies.

Aspergillosis

- Aspergillosis has been reported as the second most prevalent opportunistic fungal infection. *Aspergillus* species are universally found in humid areas, damp soil, grain, cereal, mouldy flour and organic decaying or decomposing matter. In the hospital setting, construction activities, rotten leaves or insufficient cleaning of dust can increase the risk of developing aspergillosis. *Aspergillus fumigatus* is the most familiar pathogen of the species. Human infections are also caused by less common *Aspergillus* species, such as *Aspergillus flavus*, *Aspergillus terrus*. The most common species encountered is A. flavus followed by *Aspergillus fumigatus* and *A. niger*.

Aspergillosis ulcer

Clinical presentation

- Aspergillosis generally occurs after inhalation of spores, that can result in both upper and lower respiratory tract infection-bronchopulmonary aspergillosis. From lungs, infections may spread to the brain, bone or endocardium. Paranasal sinuses, larynx, eyes, ears and the oral cavity may be involved in primary aspergillosis. *A. fumigatus* is the usual agent of sinus aspergillosis, whereas *A. flavus* is more common in invasive lesions in immunosuppressed individuals. Orofacial aspergillosis is relatively common in patients undergoing treatment for malignancies of the blood and blood-forming organs.

CRYPTOCOCCOSIS

- Cryptococcus is another very important human fungal pathogen that grows inside the host as budding yeast cells. The main characteristic feature of yeast cells of *Cryptococcus* is the formation of a polysaccharide capsule around a melanized cell wall. The capsule grows in size within the host and is considered to be the main virulence factor of *C. neoformans* because it has multiple effects on the host, including inhibiting phagocytosis by macrophages and modulating the host's innate and adaptive immune responses.

- *Cryptococcus neoformans* and *Cryptococcus gattii* are commonly considered as the causative agents of cryptococcosis. *C. neoformans* generally affects immunocompromised hosts whereas *C. gattii* is isolated more from immunocompetent individuals.

Clinical presentation

- *C. neoformans* infections usually occurs after inhalation of fungal spores from the soil and excreta of birds. In immunocompetent individuals the infection remains subclinical within the lungs. In the immunocompromised host, the fungus produces rapid disseminated infection involving central nervous system, skin, mucous membranes and many other tissues.

Diagnosis

- Histopathology varies according to the immunological status of the host. In immunocompetent hosts, typical granulomas are formed at the site of cryptococcal infection, with multinucleated giant cells containing intracytoplasmic cryptococci in budding forms. In immunosuppressed patients, proliferating cryptococci present as extra- and intracellular yeast cells with some budding forms with reactive macrophages, minor lymphocytic and neutrophilic infiltrate. The definitive diagnosis of cryptococcosis is established with periodic acid Schiff (PAS), and mucicarmine-stained preparations. The fungal cytoplasm appears bright by PAS stain and mucicarmine stains the fungal capsule. Culture and assay of serum or cerebrospinal fluid for capsular antigen is useful.

Histoplasmosis

- Histoplasmosis is caused by *Histoplasma capsulatum*. The disease can affect the lungs and cause acute or chronic respiratory problems in the immunocompromised population.. The reticuloendothelial system, gastrointestinal tract and kidneys are also affected by this fungus. Histoplasmosis may sometimes appear in a mucocutaneous form that can manifest as ulcerating or nodular lesions in the oral mucous membrane. The oral lesions may also appear granulomatous and may be painful, localized on the oral mucosa, tongue or lips. The ulcers may often resemble carcinoma or tuberculosis because of the raised and rolled borders, usually covered by a yellow or greyish membrane.

Diagnosis

- Diagnosis is usually confirmed by microscopy, culture and serology. The serum immunodiffusion assay that detects antibodies against the H and M antigens of *H. capsulatum* is reported to be a reliable diagnostic method.

Histoplasmosis ulcer

Blastomycosis

- Blastomycosis is a rare fungal disease caused by *Blastomyces dermatitidis*, a spore found in the soil, when inhaled, it can cause disseminated disease or a localized respiratory condition. When the disease affects the oral cavity, it produces ulcerating mucosal lesions as well as sessile projections, granulomatous or verrucous lesions. Small ulcers are characteristic oral manifestation and may present as a primary lesion or secondary to disseminated disease. The isolation of the fungus from clinical specimens and histopathological examination of appropriately stained sections are the definite method for establishing diagnosis. The fungus grows well in standard mycological media such as sabouraud dextrose agar SDA, potato dextrose agar or inhibitory mold agar. Classically appears as round to oval, multinucleate yeast cell with a single broad-based bud under the microscope.

SACCHAROMYCES INFECTION

- *Saccharomyces cerevisiae* (also known as "baker's yeast") is widespread in nature and is a commensal inhabiting the gastrointestinal tract of humans. *S. cerevisiae* is now included in some diet or health foods. Fungemia from *S. cerevisiae* can follow the use of live yeast capsules of *Saccharomyces boulardii* which are used as probiotics for the prevention and treatment of various diarrheal disorders.

Clinical presentation

- Lesions resemble invasive candidiasis due to the presence of esophagitis in both conditions. Fever may be present in majority of patients. Deep site involvement with necrosis and granulomatous reaction has also been reported. Intra-oral manifestations include ulcers with associated painful swallowing, dry mouth and burning sensation.

Diagnosis

- Direct Gram stain from the swab will show majority of Gram-positive budding yeast cells. The culture will give creamy-white yeast-like growth. The Gram staining from the colony will show budding yeast cells without any capsule. The organism can be identified using corn meal agar and carbohydrate assimilation test.

Thank you •

Bacterial Pathogenicity

Infection: is the invasion of the human body tissues by disease-causing agents, their multiplication, and the reaction of host tissues to the infectious agents and the toxins they produce.

Mixed infection: Several microbes grow simultaneously at the infection site.

Disease: Any deviation from health, disruption of a tissue or organ caused by microbes or their products.

CARRIER: A Person or animal with asymptomatic infection that can be transmitted to another susceptible person or animal.

Human body defenses

There are two kinds of body defenses against microbial infections:

- **humoral immunity** the aspect of immunity that is mediated by macromolecules , such as secreted antibodies, complement proteins, and certain antimicrobial peptides.
- **Cell-mediated immunity** is an immune response that does not involve antibodies, but rather involves the activation of body immunity cells like phagocytes, antigen-specific cytotoxic T-lymphocytes.

According to its way of living bacteria can be classified to

1. **Nonpathogenic:** A microorganism that does not cause disease.
2. **Opportunistic pathogen:** An agent capable of causing disease only when the host's resistance is impaired (e.g. when the patient is "immunocompromised).
3. **Pathogenic bacteria:** is parasitic bacteria that are the causative agents of bacterial infections.
4. **Saprophytic bacteria:** which live freely in the soil and feed on decaying organic matters.
5. **Commensals:** Are parasitic bacteria live on external or internal surfaces of the body without causing disease, these bacteria may even be beneficial to the host e.g. commensals of the gut digest polysaccharides and are source of certain vitamins, these bacterial flora also compete with pathogenic bacteria for nutrition thus inhibiting their growth.

Bacterial Pathogenicity:

refers to the ability of an organism to cause disease, using its virulence factors**.** **Virulence** usually refers to the degree of pathogenicity within a group or species of microorganisms. virulence of a microorganism is not generally attributable to a single factor, but depends on several parameters that are related to the organism, the host, and the dynamic interaction between them. Bacterial virulence, can be measured by bacterial **infectivity** (their ability to initiate an infection) and the **severity** of the condition produced.

In the lab, Virulence can be designated as LD_{50} or ID_{50} (These values are determined by inoculation of laboratory animals):

the LD_{50} (50% lethal dose) is the number of organisms needed to kill half the hosts, and ID_{50} (50% infectious dose) is the number needed to cause infection in half the hosts.

Pathogenicity depends on:

1- Virulence factors (Adherence factors, Invasiveness, Toxin production).

2- Number of initial organisms.

3- Immune status.

Table 5.2 Examples of surface virulence factors which interfere with host defences

Organism	Virulence factor	Used in vaccine
Bacteria		
Streptococcus pneumoniae	Polysaccharide capsule	Yes
Streptococcus pyogenes	M protein	No
Staphylococcus aureus	Protein A	No
Neisseria meningitidis	Polysaccharide capsule	Yes
Haemophilus influenzae	Polysaccharide capsule	Yes
Klebsiella pneumoniae	Polysaccharide capsule	No
Escherichia coli	Protein pili	No
Salmonella typhi	Polysaccharide capsule	No
Mycobacterium tuberculosis	Mycolic acid cell wall	No
Fungi		
Cryptococcus neoformans	Capsule	No

STAGES OF PATHOGENICITY

1-Transmission

2-Attachment (adhesion, adherence).

3-Colonization and multiplication of microorganism.

4-Avoidance of host defense mechanisms like phagocytosis.

5-Damage of host cells by:

A- Invasiveness.

B -Toxin production.

C- Both of them.

TRANSMISSION Most infections are acquired by transmission from external sources, they are **exogenous** in origin. Others are caused by members of the normal flora behaving as opportunist pathogens, i.e. they are **endogenous** in origin. Transmission can be by:

- inhalation- the airborne route
- ingestion - faecal contamination of food and water.
- Inoculation - by sexual contact, contaminated needles, skin contact, blood transfusions or biting insects.

There are four important portals (or gates) of pathogens

1- Skin.

2- Respiration.

3- Gastrointestinal tract.

4- Genitourinary tract.

Table 5.1 Portals of entry of some common pathogens

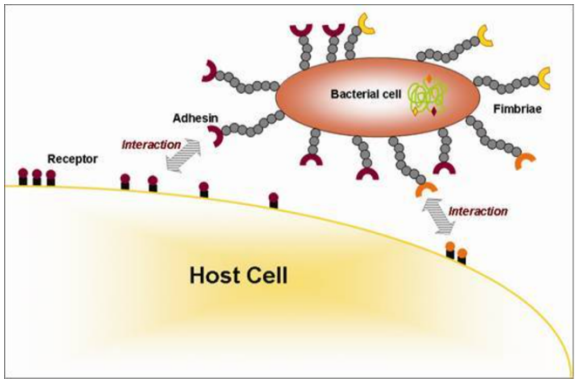
Portal of entry	Pathogen	Disease
Skin	*Clostridium tetani*	Tetanus
	Hepatitis B virus	Hepatitis B
Respiratory tract	*Streptococcus pneumoniae*	Pneumonia
	Neisseria meningitidis	Meningitis
	Haemophilus influenzae	Meningitis
	Mycobacterium tuberculosis	Tuberculosis
	Influenza virus	Influenza
	Rhinovirus	Common cold
	Epstein–Barr virus	Infectious mononucleosis
Gastrointestinal tract	*Shigella dysenteriae*	Dysentery
	Salmonella typhi	Typhoid fever
	Vibrio cholerae	Cholera
	Hepatitis A virus	Infectious hepatitis
	Poliovirus	Poliomyelitis
Genital tract	*Neisseria gonorrhoeae*	Gonorrhoea
	Treponema pallidum	Syphilis
	Human immunodeficiency virus (HIV)	Acquired immune deficiency syndrome (AIDS)
	Candida albicans (fungus)	Vaginitis

Adherence to host surfaces.

Adherence is the first step in the infection. Unless organisms have the ability to stick or adhere to host surfaces they will be unable to cause infection. Some bacteria and fungi have specialized structures or produce substances that facilitate their attachment to the surface cells (e.g. dentures, artificial heart valves), thereby enhancing their ability to colonize and cause disease. These adherence mechanisms are critical for organisms that attach to mucous membranes; mutants that lack these mechanisms are often non-pathogenic (e.g. the hair-like pili or Fimbriae, of *Neisseria gonorrhoeae* and *Escherichia coli* mediate their attachment to the urinary tract epithelium; the extracellular polysaccharides of *Streptococcus mutans* help it adhere to enamel surfaces).

Adherence factors.

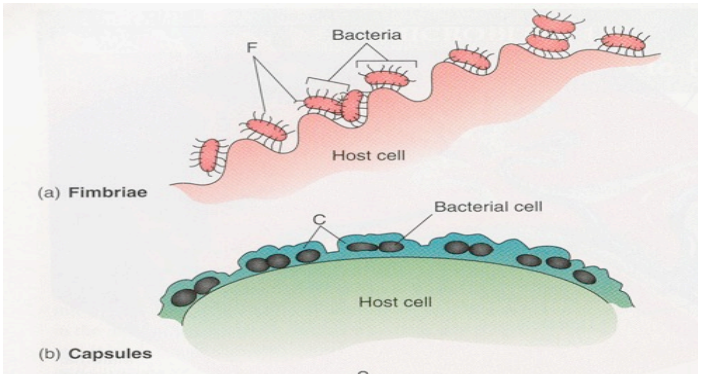
1-Fimbriae: Are the most common adhesion molecules e.g. *Neisseria gonorrhoeae* and *E coli* mediate the attachment to cell surfaces.



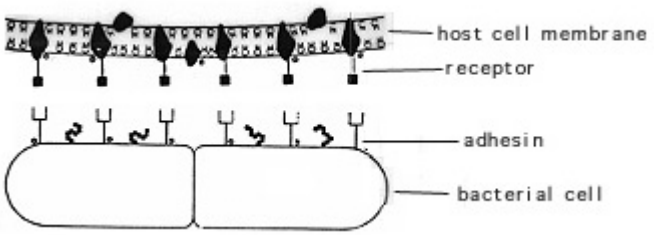
2- The **filamentous haemagglutinin adhesin (FHA)** is a large, filamentous protein that serves as a dominant attachment factor for adherence to host ciliated epithelial cells of the respiratory tract.

3-Exopolysaccarides.Present on the surface of some-gram positive bacteria are also involving in adhesions.

4- Flagella act as adhesion *in Vibrio cholerae* and *Campylobacter jejani*.



5- In addition to above types of adherence factors **Specific adherence** involves permanent formation of many specific lock- key bonds between complementary molecules on each cell surface.



Colonization and invasion:

For many pathogenic bacteria, the initial interaction with host tissues occurs at a mucosal surface and then colonization is started. This allows the establishment of infection that may remain localized or may subsequently spread to other tissues in a process called **invasion**. Cell invasion confers the ability to avoid humoral host defence mechanisms .

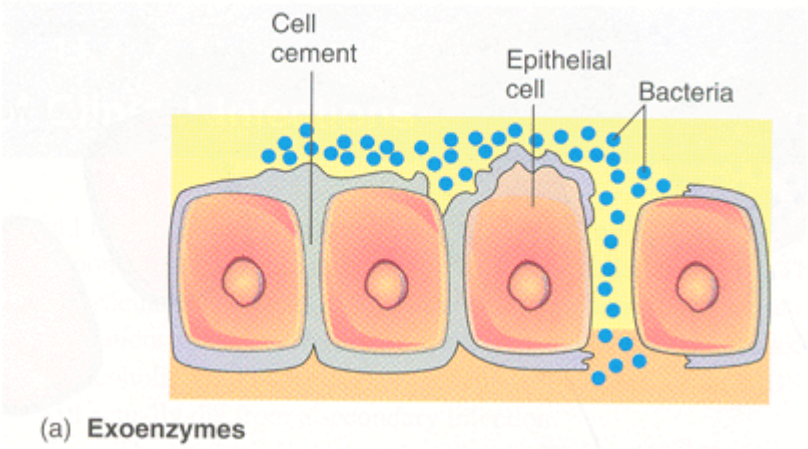
AGGRESSINS

In order to survive and multiply within the host, many organisms produce a variety of substances that allow them to avoid host defense mechanisms. These substances, termed aggressins, include capsules and extracellular slime substances, surface proteins, surface carbohydrates, enzymes, toxins, and other small molecules. The capsular structures of some bacteria enable the organisms to avoid phagocytosis by preventing interaction between the bacterial cell surface and phagocytic cells or by concealing bacterial cell surface components that would otherwise interact with phagocytic cells or complement and lead to ingestion. Some organisms produce capsules that are structurally similar to host tissues and,

therefore, are not recognized as foreign by the body defense mechanisms. Organisms that possess capsules behave as aggressins include S. *aureus, S. pneumoniae, N. meningitidis, H. influenzas* type b, *K. pneumoniae* .

INVASIVENESS

These are mechanisms that give bacteria its ability to invade tissues, multiply and spread rapidly (bacterial invasion). Invasiveness of bacteria plays a critical role in their pathogenesis by secretion of bacterial enzymes. Most are enzymes affecting physical barriers like tissue matrices and cell membranes. In this way, the bacterium can quickly spread through extracellular spaces.



(a) **Exoenzymes**

A few examples are:

● **a hemolysin** or **listeriolysin O**: Which injects into the membrane of the vacuole and causes the formation of pores (e.g. that caused by *Listeria monocytogenes)* then enters the cytoplasm of the cell, where it continues to grow and multiply, after escaping the toxic environment of the phagolysosome.

•**Collagenase :** It breaks down collagen fibers & promote spread of infection.

• **Coagulase**: Produced by *Staphylococcus aureus,* accelerates the formation of a fibrin clot (from fibrinogen). It helps protect the organisms from phagocytosis by walling off the infected area and by coating the organisms with a fibrin layer.

●**Streptokinase** and **staphylokinase :** produced from Group A streptococci and staphylococci that hydrolyze fibrin clots, which also facilitate the spread of organisms in the tissues.

• **Immunoglobulin A (IgA) protease**: Degrades protective IgA on mucosal surfaces, allowing organisms such as *N gonorrhoeae, Haemophilus injluenzae* and *Streptococcus pneumoniae* to adhere to mucous membranes.

TOXIGENICITY

Toxin is a protein or conjugated protein produced by some pathogenic bacteria that is highly poisonous for other living organism. The ability of microorganism to produce a toxin that contributes to the development of disease called **toxigenicity.** Endotoxins are toxic to most mammals, and can be lethal if encountered in too high a dose. Toxins are of two categories: endotoxins and exotoxins.

Endotoxins

Endotoxins are the cell wall lipopolysaccharides of Gram-negative bacteria (both cocci and bacilli) and are not actively released from the cell, it is released after the cell death. Endotoxins cause fever, shock and other generalized symptom s.

It is an outer membrane chemical moiety consisting of three sections:

1-A toxic lipid (Lipid A) anchored in the outer membrane,

2-An immunogenic polysaccharide core, and

3-An O antigen proteins of oligosaccharides at the extracellular surface.

Exotoxins

Both Gram-positive and Gram-negative bacteria secrete exotoxins. Exotoxins in particular can cause disease in distant parts of the body as a result of diffusion of the toxin via systemic routes (e.g. tetanus bacillus infecting a lesion in the foot produces an exotoxin which causes 'lockjaw' or spasm of masseter muscles on the face).

Bacterial exotoxins can be broadly categorized as:

• neurotoxins

• enterotoxins

• miscellaneous exotoxins.

Neurotoxins. Tetanus toxin, diphtheria toxin and botulinum toxin are all neurotoxins and their action is mediated via neuronal pathways.

Enterotoxins. These toxins act on the gut mucosa and cause gastrointestinal disturbances.

Escherichia coli enterotoxin is of two types: one heat-labile and one heat-stable.

Miscellaneous exotoxins. these exotoxins are produced by *Clostridium perfringens* and other species of clostridia that cause gas gangrene.

Antiphagocytic (Survival Inside of Phagocytes)

Many bacterial pathogens are rapidly killed once they are ingested by polymorphonuclear cells or macrophages. Some pathogens evade phagocytosis or leukocyte microbicidal mechanisms by adsorbing normal host components to their surfaces.

For example, *Staph..aureus* has surface protein A. Other pathogens have polysaccharide capsules that impede phagocytosis, e.g., *Streptococcus pneumoniae, N meningitidis.*

Streptococcus pyogenes (group A streptococci) have M protein, *N gonorrhoeae*(gonococci) have pili.

Most of these antiphagocytic surface structures show much antigenic heterogeneity. For example, there are more than 80 pneunococcal capsular polysaccharide types and more than 60 M protein types within group A *streptococci*.

A few bacteria (e.g., *bordetella*) produce soluble factors or toxins inhibit chemotaxis by leukocytes and thus evade phagocytosis by a different mechanism. Bacteria that can resist killing and survive or multiply inside of phagocytes are considered intracellular parasites. In this case, the environment of the phagocyte may be protecting bacteria during the early stages of infection or until they develop more virulence factors.

The role of bacterial biofilms

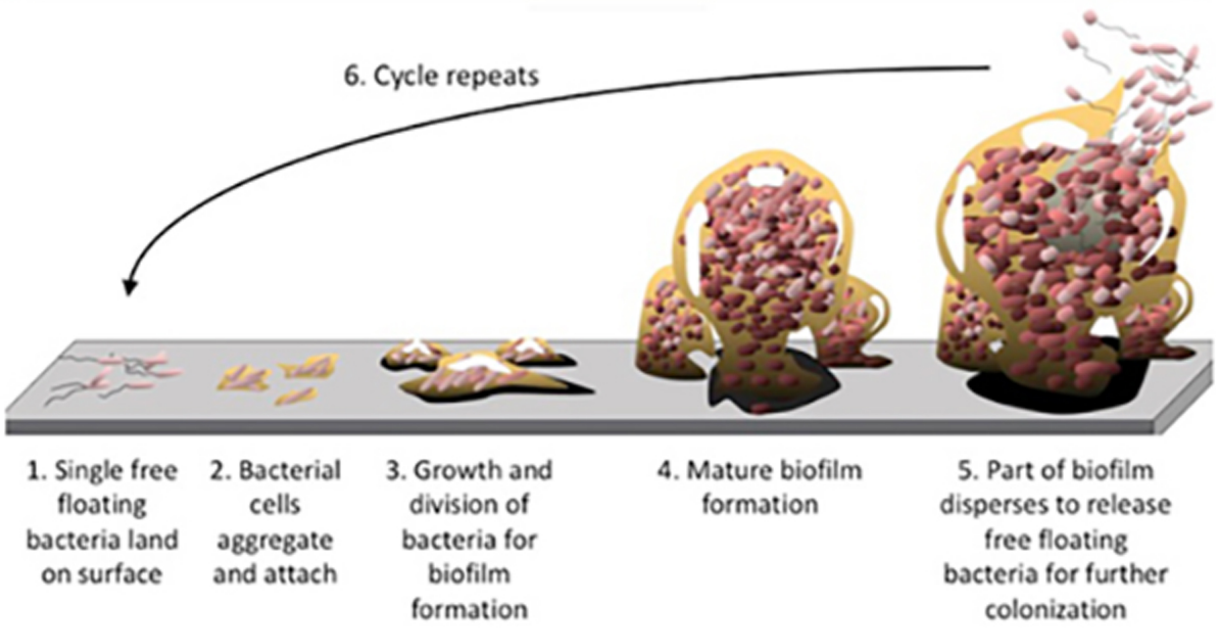
A biofilm is an aggregate of interactive bacteria attached to a solid surface or to each other and encased in an exopolysaccharide matrix. Biofilms form a slimy coat on surfaces and throughout nature. Bacteria of single species may coaggregate to form a biofilm. Fungi- including yeasts are occasionally involved.

Biofilms are:

- -formed when microbes adhere to each other and to the surface
- -each microbe secretes glycocalyx substances allowing other microbes to adhere; large mass is formed

the biofilm is resistant to disinfectants and antibiotics (outer layer protects inner layers), which makes serious problems for patients with catheters and surgical implants: serves as chronic reservoir.

Biofilms are important in human infections that are persistent and difficult to treat. A few examples include *Staphylococcus epidermidis* and *Staphylococcus aureus* infections of centralvenous catheters, eye infections such as occur with contact lenses and intraocular lenses, in dental plaque, and with *Pseudomonas aeroginosa* airway infections in cystic fibrosis patients.



Pathogenesis of viral infection

Pathogenesis is the process by which an infection leads to disease. Pathogenic mechanisms of viral disease include

(1) implantation of virus at the portal of entry,

(2) local replication,

(3) spread to target organs (disease sites), and

(4) spread to sites of shedding of virus into the environment.

Factors that affect pathogenic mechanisms are

(1) accessibility of virus to tissue,

(2) cell susceptibility to virus multiplication, and

(3) virus susceptibility to host defenses.

Virions (free viruses) implant onto living cells mainly via the respiratory, gastrointestinal, skin-penetrating, and genital routes although other routes can be used. The final outcome of infection may be determined by the dose and location of the virus as well as its infectivity and virulence.

Most virus types spread among cells extracellularly, but some may also spread intracellularly. Establishment of local infection may lead to localized disease and localized shedding of virus.

Viremic: The most common route of systemic spread from the portal of entry is the circulation, which the virus reaches via the lymphatics.

The incubation period is the time between exposure to virus and onset of disease. During this usually asymptomatic period, implantation, local multiplication, and spread (for disseminated infections) occur.

Depending on the balance between virus and host defenses, virus multiplication in the target organ may be sufficient to cause disease and death. (e.g. specific preference cells for rhinoviruses are upper respiratory epithelium and for human immunodeficiency virus (HIV) are CD4 T Lymphocytes)

Diverse viruses may be shed at virtually every site.

Pathogenesis of fungal infection

Fungal disease, particularly its life-threatening extreme, is relatively rare despite the many species of fungi present in the environment and on the human body surface. Most fungal infections appear to require a breach in host defenses in order to become established. Yeasts often cause mucosal inflammation following alteration of either vaginal or gastrointestinal flora. Dermatophytic fungi cause a variety of skin conditions but rarely cause more invasive disease in immunocompetent patients because they are restricted to the skin.

Pathogenesis of parasitic infections

Protozoal and helminth infections have a complex pathogenesis, which is best understood by referring to the parasite's life cycle. Some protozoal and helminth infections require transmission by a disease vector. The vector is often an arthropods. The development of disease depends on a three-way relationship between microorganism, vector and human victim in these infections.

In developed countries, parasitic infections are most common in international travelers, the sexually active, immunocompromised patients and poor people.

Opportunist infections

If an organism is capable of causing disease in an apparently healthy individual, it is clearly aggressively pathogenic. If it is normally incapable of causing disease but can do only when the human body immunity is compromised in some way, in this case infection called opportunist infection. These types of infections have a particular importance in hospitals patients and immunocompromised patients.

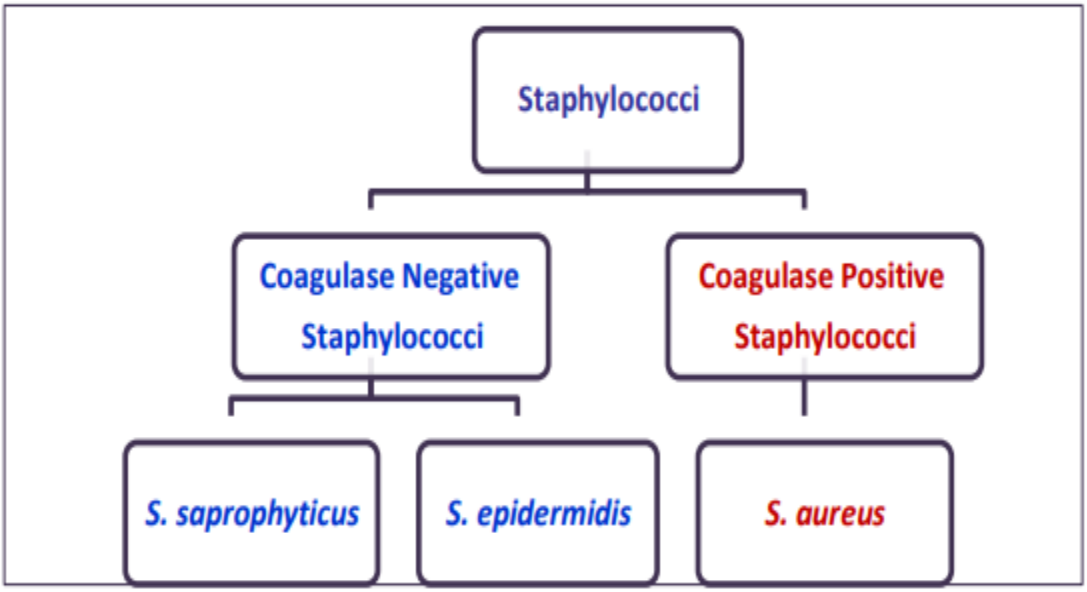
Staphylococci

Staphylococci are members of the Micrococcaceae family. They are classically considered extracellular, pyogenic pathogens because of their ability to induce abscess formation.

Staphylococcus: Pathogenic or commensal

Micrococcus: Free-living saprophytes

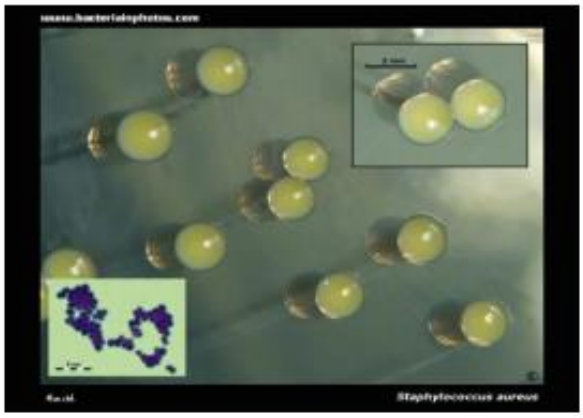


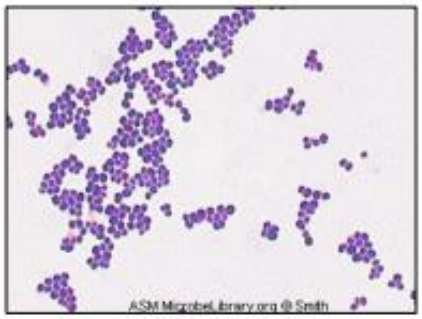
General Phenotypic Characteristics of Staphylococci

Staphylococci are

Gram-positive Cocci, which appears as grape- like clusters when viewed through a microscope.

Staphylococci





-oxidase-negative

-Grow at 15 % NaCl concentrations.

- Facultative anaerobes (respiration or fermentation), fermentation of glucose produces mainly lactic acid.

-Optimum temperature at 37°C, can grow at a temperature range (15 to 45 c). They form round often beta-hemolytic colonies on agar. The aureus refers to the gold color of the colonies.

- All staphylococci are catalase positive. Catalase converts H_2O_2 to H_2O and O_2

The **coagulase**(Coagulase converts fibrinogen to fibrin) and manifold fermentation tests are used to distinguish S. aureus from other staphylococcal species -.

Non Fastidious Non motile Non spore forming.

Medically Important Staphylococci Species:

Coagulase Positive Staphylococci (CoPS) –

S. aureus colonizes mainly nasal passage as normal flora, but it may be found in other sites (skin, mucous membranes, oral cavity & gastrointestinal tract) - Always considered a potential pathogen - Causes nosocomial infections.

Carriage is increased in populations known to be at risk of staphylococcal disease including dialysis patients, diabetics and HIV-infected subjects. Staphylococci cause infection either as a result of autoinoculation or by transmission from a carrier to a patient.

Coagulase Negative Staphlyococci (CoNS)

-are part of normal flora of human skin and mucous membranes

- relatively low virulence

- frequently involved in nosocomial and opportunistic infections

- Clinically significant infection associated with endocarditis, joint infection, wound infections, bacteremia, Urinary tract infections (UTI).

- S. epidermidis is an inhabitant of the skin and mucous membranes, mostly nonpathogenic & may play a protective role in humans as normal flora.

- In contrast to S. aureus, little is known about mechanisms of pathogenesis of S. epidermidis infections.

- Adherence and colonization of catheters by S. epidermidis is a crucial step in the initiation of foreign body infections.

- The production of biofilm, a significant determinant of virulence for S. epidermidis.

- S. saprophyticus is a leading cause of cystitis in young women. And shares of urinary tract infection

Pathogenesis of S. aureus

S. aureus causes a variety of suppurative (pus-forming) and toxigenic infections in humans. It causes:

- **Superficial skin lesions such as Boils, furuncles, abscess**

Because of their presence as commensals on the skin and other sites, both coagulase positive and negative bacteria frequently cause prosthetic device (e.g. intravascular catheters) related infections. Establishment of infection in general requires an ordered sequence of events that involves adherence, colonization, invasion, spread, as well as the host response to this process.

- **More serious skin** infections such as Impetigo (bubble-like swellings that can break and peel away; common in newborns) Staphylococcal scalded skin syndrome (SSSS) or Ritter's disease (relatively rare); (toxin induces bright red flush, blisters, then desquamation of the epidermis)

- **Serious infections (Deep)** such as Pneumonia (infections in the lung), Osteomyelitis (Localized infection of bone), endocarditis, meningitis, skeletal

muscle, urinary tract infections. S. aureus is a major cause of hospital acquired (nosocomial) infections Surgical wounds and infections associated with medical devices.

- **Toxigenic infections** such as S. aureus causes food poisoning by releasing heat stable enterotoxins into food. It can produce toxic shock syndrome (leading to shock and organ failure) by release of superantigens into the blood stream.

The superantigens are T cell mitogens. Disease is due to the ability of these toxins to bind antigen presenting cells MHC 2 molecule outside the peptide groove. The superantigens then bind T cells via the variable region resulting in massive T cell activation and the release of large quantities of cytokines – a "cytokine storm" including IL-1, IL2, TNF, and interferon gamma. The result is a multiorgan disease similar in clinical presentation to septic shock with significant morbidity and mortality.

- **Serious consequences of staphylococcal infections (Systematic infections**) occur when the bacteria invade the blood stream. A resulting septicemia may be rapidly fatal or bacteremia

S. aureus expresses many potential virulence factors

(1) Surface proteins that facilitate bacterial adherence to host cell surfaces. These surface proteins facilitate attachment to molecules found in the extracellular matrix including fibronectin, fibrinogen, and collagen. They may help explain the tropism of this bacterial species to invade particular tissue sites

(2) Invasins Promote bacterial spread in tissues (leukocidin, kinases, hyaluronidase). Hyaluronidases hydrolyze hyaluronic acids and may contribute to tissue breakdown and spread of staphylococci across tissue barriers

(3) DNase Digests DNA

(4) Lipases Digest oils; enhances colonization on skin .

(5) Surface factors Avoidance of host defenses; Inhibit phagocytic engulfment (capsule, Protein A).

- The majority of clinical isolates of S aureus express a surface polysaccharide (microcapsule) because it can be visualized only by electron microscopy. S. aureus strains isolated from infections express high levels of the capsule but rapidly lose it when cultured in the laboratory.

- Protein A: binds IgG antibody in the wrong orientation (Fc region), which disrupts opsonization and phagocytosis.

(6) Biochemical properties Enhance survival in phagocytes Staphyloxanthin; carotenoid pigment which responsible for golden colonies, and it has an antioxidant action that helps bacteria to evade reactive oxygen by the host immune system. Catalase production.

(7) Immunological disguises (Protein A, coagulase)

(8) Membrane-damaging toxins Lyse eukaryotic cell membranes Hemolysin (α, β, γ, δ) lysis red blood cells. Leukocidin; (lysis neutrophils and macrophages).

(9) Exotoxins Damage host tissues or provoke symptoms of disease - Staphylococcal enterotoxins; (SEA-G); food poising (nausea, vomiting, diarrhea). - Toxic shock syndrome toxin (TSST); induces fever, vomiting, shock, organ damage**.**

Exfolioative toxins (ETs);

responsible for Staphylococcal scalded skin syndrome (SSSS); separates the epidermis from the dermis. - Panton-Valentine Leukocidin (PVL) cytotoxin creates pores in the membranes of infected cells. It is associated with severe necrotizing pneumonia in children.

(**10**) Inherent & acquired resistance to antimicrobial agents (Penicillinase-inactivates penicillin).

Beta-lactamases are released by staphylococci and can hydrolyze the beta-lactam ring of penicillins and cephalosporins rendering the antibiotics useless.

Host Defense against Staphylococcal Infections

Phagocytosis Neutrophil is the primary cellular defenses of innate immunity against Staphylococcal infections. Antibodies are produced which neutralize toxins and promote opsonization. Staphylococci may be difficult to kill after phagocytic engulfment because they produce catalase which neutralize oxygen and superoxide, which are primary phagocytic killing mechanisms within the phagolysosome

Treatment Hospital acquired infection of S. aureus is often caused by antibiotic resistant strains (e.g. MRSA) and can be treated with vancomycin or an alternative. The term MRSA refers to Methicillin resistant S. aureus and

related beta-lactam antibiotics (e.g. penicillin, oxacillin, amoxacillin). Some MRSA are resistant to vancomycin (VRSA). The infections have been treated with combination therapy using sulfa drugs and or rifampin. (CoNS); produce an enzyme called beta lactamase that makes them resistant to methicillin and oxacillin. Vancomycin is the most common antibiotic used to treat infections caused by CoNS-; if they not resistant. Rifampin and gentamicin may be added to prevent antibiotic resistance.

Vaccines :-No vaccine is generally available that stimulates active immunity against staphylococcal infections in humans.

Staphylococci and micrococci in Oral cavity

Staphylococci and micrococci are also not commonly isolated in large numbers from the oral cavity although the former are found in denture plaque, as well as in immunocompromised patients and individuals suffering from a variety of oral infections .Although these bacteria are not usually considered to be members of the resident oral microflora, they may be present transiently, and they have been isolated from some sites with root surface caries and from some periodontal pockets that fail to respond to conventional therapy. Interestingly, this is in sharp contrast to other surfaces of the human body in close proximity to the mouth, such as the skin surface and the mucous membranes of the nose, where they are among the predominant components of the microflora. This finding emphasizes the major differences that must exist in the ecology of these particular habitats.

Philip D Marsh & Micheal V Martin

Sterilization:

Sterilization and disinfection are important for both personnel safety and patient safety. Sterilization and disinfection are important to prevent the chain of infection in the dental office. The chain of infection is a complex series of events that requires that all of the following conditions be present.

Sterilization:- Is defined as the process by which an article, surface or medium is freed of all living microorganisms either in the vegetative or in the spore form.

Disinfection:- It is the destruction or removal of all pathogenic organisms to a level which seems to be no longer harmful to health

Contamination:-The presence of microorganisms on a body surface or on inanimate articles or substances.

Sanitation:-The process by which the number of microorganisms on inanimate objects is reduced to a safe level. It does not imply freedom from microorganisms, and generally refers to a cleaning process

Asepsis:- A condition in which living pathogenic microorganisms are absent.

Antiseptic:-A substance that prevents or arrests the growth of action of microorganisms either by inhibiting their activity or by destroying them.Term used especially for preparations applied topically to living tissues

Infection Control:-The selection and use of procedures and products to prevent the spread of infectious diseases.

Bactericidal:- These are agents which are able to kill bacteria.
Bacteriostatic:- These agents prevent the multiplication of bacteria

The chain of infection is something that you think about when you are choosing disinfection and sterilization of items that are used in patient care or in the area around which patient care is provided. The chain of infection is: -

- An entrance through which the pathogen may enter the host.

- A susceptible host is one who is not immune or has compromised immunity.

- A sufficient number of pathogens, or infection-causing organisms, must be present to produce infection. This is called the infectious dose. This varies for different infections or diseases. There must be a reservoir or source that allows the infectious agent to survive and multiply (e.g., blood).

- There is a mode of transmission from the source to the host.

When all the above events happen together, this is considered the **"chain" of infection**. Effective infection control strategies prevent infection or disease transmission by interrupting one or more links in the chain of infection.

A mode of transmission is the method of transmission of infectious agents.

Different infections are transmitted in different ways more efficiently by different modes. Specifically, some modes are more efficient at transmission of infection than others. For example, with bloodborne infections, percutaneous or beneath-the-skin entry, is a highly efficient way to transmit infections. Intact skin is a fairly good barrier for infection control and is not a very efficient way to transmit infection.

Cleaning:-

Is the most important step in all decontamination processes. Cleaning involves the physical removal of debris and reduces the number of microorganisms on an instrument or device. If visible debris or organic matter is not removed, it can interfere with the disinfection or sterilization process. Use appropriate protective barriers such as heavy-duty utility gloves, masks, and protective eyewear when cleaning and disinfecting surfaces. Examples of cleaners include ultrasonic cleaners, instrument washers and washer disinfectors.

There are three categories of patient-care items, depending on their intended use and the potential risk of disease transmission for dental instruments and devices.

• **Critical items** touch sterile areas of the body, such as those in an incision or in deep tissues. Dental equipment which touch sterile areas of the body, such as bone and blood vessels or penetrates the mucous membrane of the mouth is classified as critical. The latter includes tongue or gingival tissues. Examples of critical items include surgical instruments, scalpel blades, periodontal scalers and surgical dental burs. Sharps injury with contaminated needles or scalpels carry the greatest risk of infection of bloodborne pathogens for oral care personnel.

• **Semi-critical** items are contact-only mucous membranes and do not penetrate soft tissues. As such, they have a lower risk of transmission. Because most items in this category are heat-tolerant, they should be heat sterilized between patient uses. For heat-sensitive instruments, high-level disinfection is appropriate. Examples of semi-critical instruments include dental mouth mirrors, amalgam condensers and impression trays. •

Non-critical items contact intact skin. These include, among other things, blood-pressure cuffs and X-ray heads. Special cases are those clinical surfaces or frequently touched environmental surfaces.. Non-critical items pose the least risk for transmission of infection. Dental handpieces are a special case. Even though they do not penetrate soft tissue, it is difficult for chemical germicides to reach the internal parts of handpieces, they should be heat sterilized using a steam autoclave or chemical vapor sterilizer.

Biological indicators:- Biological spore tests use biological spores to assess the sterilization process directly. Biological indicators measure the ability to determine if the sterilization method is effective and if sterilization conditions have been met. This is a standardized preparation of bacterial spores on or in a carrier. They must be placed in the most difficult site for sterilant penetration, and a positive indicator is a process failure.

Disinfection:-

Disinfection is different from sterilization in that sterilization kills all life forms, including spores. Disinfection is a less effective process than sterilization

Three Levels of Disinfection

_High .

_Intermediate .

_Low .

How to choose a disinfectant

Most disinfectants specify that surfaces should be kept wet for 10 minutes. Hierarchy of resistance to organisms for liquid chemical sterilants/disinfectants (high to low):-

*Spores

*Mycobacteria tuberculosis var. bovis.

*Non-lipid or small viruses.

*Fungi.

*Vegetative bacteria.

*Lipid or medium sized virus .

Types of Disinfectants

High-level disinfectant – Utilizes a liquid chemical sterilant and a process that kills all life forms including bacterial spores and inactivates Mycobacterium tuberculosis var. bovis.

Intermediate-level disinfectant – Utilizes a liquid chemical sterilant and a process that kills all life forms but not bacterial spores and inactivatesMycobacterium tuberculosis var. bovis

_Low-level disinfectant – Inactivates vegetative bacteria, some fungi medium-large viruses, viruses with lipid-containing envelopes. These include quaternary ammonium compounds, some phenolics, some iodophors

. Hospital disinfectants are those that have demonstrated potency against Pseudomonas aeruginosa Staphylococcus aureus and Salmonella cholerasuis

In general, cleaning and removal of microorganisms is as important as the disinfection process itself for surfaces. Blood or other patient materials left on surfaces can interfere with the disinfecting process.

Because of their toxic nature, the use of sterilants or high-level disinfectants on environmental surfaces is not recommended. Clinical contact surfaces, including a light handle, countertop, bracket tray, dental chair, and door handles are example of clinical contact surfaces. Examples of housekeeping surfaces are walls, sinks, and floors

Sterilization

1.1 Wet heat (Autoclaving)

Autoclave :-Sterilization: Autoclaves provide a physical method for disinfection and sterilization. They work with a combination of steam, pressure and time. Autoclaves operate at high temperature and pressure in order to kill microorganisms and spores.

Temperatures at 100 C (boiling)

¬ Vegetative bacteria are killed almost immediately at 90-1000 C, but sporing bacteria require prolonged periods of boiling.

¬ Boiling water is not considered as a sterilizing agent because destruction of bacterial spores and inactivation of viruses cannot always be assured.

It is considered as a method for disinfection

¬ A minimum exposure period of 30min. is recommended to kill vegetative bacteria.

¬ Sodium bicarbonate 2% conc. is added to increase the efficiency of process

Sterilization of

1- Culture media (MacConKey agar, Nutrient broth …etc)

2-Aqueous solution (Normal saline , phosphate buffer saline … etc)

3-Dressing material (lab cot)

4-Linen, gloves ….etc

By using autoclave system at 15 pounds per square inch (psi)prossure equivalent to 121 ^{o}C in 15-20 minutes .

The laboratory Autoclave:-consists of

1-a vertical or horizontal cylinder of gun metal or stainless steel in a supporting frame .

2-Lid is fastened by screw clamps .Lid bears a pressure gauge and steam release valve (safety valve) .

3-Heating is done by electricity ,

Equipment used in the experiment

1-Water is added on the bottom.

2-The lid is closed ,steam pressure rises inside and when it reached the desired set level(15 psi) the safety valve opens .

3-In this point the holding time (15 minutes) is counted .

4- After 15 min. the heating is stopped ,autoclave cool ,the lid is now opened and the sterilized articles removed .

Sterilization control:-

Two types of controls are available .

1-Biological control:- An envelope containing a filter paper strip impregnated with 10^{6} spores of ***Bacillus stearothermophilus***. after sterilization is over the strip incubated in tryptone soy broth aerobically at 37^{o}C for five days .No growth proper sterilization.

2-Chemical control :- A Browne's tube containing red solution is placed within the load .A change of color of the solution to green indicates proper sterilization .

Fig.1:Autoclave

1.2. DRY HEAT (Flaming, baking)

Dry heat tends to kill microbes by oxidation of cellular components. This requires more energy than protein hydrolysis so higher temperatures are required for efficient sterilization by dry heat.

Aim of test:-sterilization of

1-All glass instruments, test tube , petri dishes , pipettes and flasks

2-Metal instruments such as forceps ,scissors and scalpel

3- Materials such as oils jellies and powder .

Not suitable for material like fabrics , protein, sugars , damaged by heat .

1.2.2. Hot air oven: hot air oven is electrically heated and is fitted with a thermostat that maintained the chamber air at a chosen temperature

Table (1)

Mode of sterilization	Instrument	Temperature and time	Sterilization of
Below 100 ^{o}C	Water-bath	56 ^{o}C for 1 hr. or 65-75 for 10 min.	Serum, body fluids, vaccines
At 100 ^{o}C	Boiling water-bath	100 ^{o}C for 10-20 min.	Glass, metal and rubber items .
Steaming at 100 ^{o}C	Arnold steamer	100 ^{o}C for 20 min. on 3 successive days .	Culture media containing sugars and gelatin
Above 100 ^{o}C	Autoclave	121 ^{o}C for 15-20 minutes	Culture media and aqueous solution, dressing material ,

			lines , gloves .. etc

1.3. FILTRATION

Filtration is a great way of quickly sterilizing solutions without heating.

1.3.1. Equipment used in the experiment

1-Filters with a pore diameter that is too small for microbes to pass through.

2-Glass funnels made from heat-fused glass particles or, more commonly these days, membrane filters made from cellulose esters. For removal of bacteria, filters with an average pore diameter of 0.2 micrometer is normally used.

*viruses and phage can pass through these filters so filtration is not a good option if these are a concern.

1.4. SOLVENTS

Ethanol is commonly used as a disinfectant, although since isopropanol is a better solvent for fat it is probably a better option.

Both work by denaturing proteins through a process that requires water, so they must be diluted to 60-90% in water to be effective.

Again, a it's important to remember that although ethanol and IPA are good at killing microbial cells, they have no effect on spores.

1.5. RADIATION

UV, x-rays and gamma rays are all types of electromagnetic radiation that have profoundly damaging effects on DNA, so make excellent tools for sterilization.

The main difference between them, in terms of their effectiveness, is their penetration.

1- **Ultra violate light :¬** When microorganisms are subjected to UV light, cellular DNA absorbs energy & adjacent thymine molecules link together. Linked thymine molecules are unable to position adenine on m RNA molecules during the process protein synthesis thereby replication of chromosome will be impaired. The damaged organism can no longer produce critical proteins or reproduce.

¬ UV light is used to limit airborne or surface contamination in a hospital room, pharmacy food service operation. UV light does not penetrate liquids or solids and it may cause damage to the human skin.

2-X-rays and gamma rays are far more penetrating, which makes them more dangerous but very effective for large scale cold sterilization of plastic items (e.g. syringes) during manufacturing.

Microwaves

¬ Microwaves have a wavelength longer than UV light.

¬ In a microwave oven waves are absorbed by water molecules.

¬ The molecules are set into a high speed motion, and the heat of friction is transmitted to food, which become hot rapidly.

Laser

– Light Amplification by Stimulated Emission of Radiation

¬ Can be used to sterilize instruments & the air in operating rooms, as well as for a wound surface.

Ultrasonic vibrations ¬ They are high frequency sound waves beyond the range of human ear.

¬ When propagated in fluids ultrasonic vibrations cause formation of microscopic bubbles or cavities and the water appears to boil.

¬ Call this cold boiling.

Microorganisms in the fluid are quickly disintegrated by the external pressures.

¬ The current trend is to use ultrasonic as a cleaning agent to follow the process by sterilization in an autoclave

Some of important instruments of microbiological lab:-

Electric oven : used for sterilizing glass ware and tools that need drying heating (150 ^{o}C) for2hrs.

Autoclave : To sterile the culture media and some of chemical solutions which need wet heating with (121^{o}C) and pressure (15 par Inch 2) for suitable time.

Incubator: for provide the suitable temperature to grow the bacteria most bacterial species grow under 37^{o}C for (18-48 hrs).

Compound Microscope: is a vital instrument in microbiological Lab. to identification the bacteria by it is magnification ability.

Refrigerator: Used for storage the culture media ,bacteria growth culture and other material that low temperature.

Hood: for availing an uncontamination environment during the laboratory work.

Gas Burner: used to sterile the mineral tools such as loop ,needle and nozzle bottles or flask.

Sensitive Balance : for weighting the powders

Loop & Needle : platinum wires used for transporting culturing and inculating the bacterial growth .

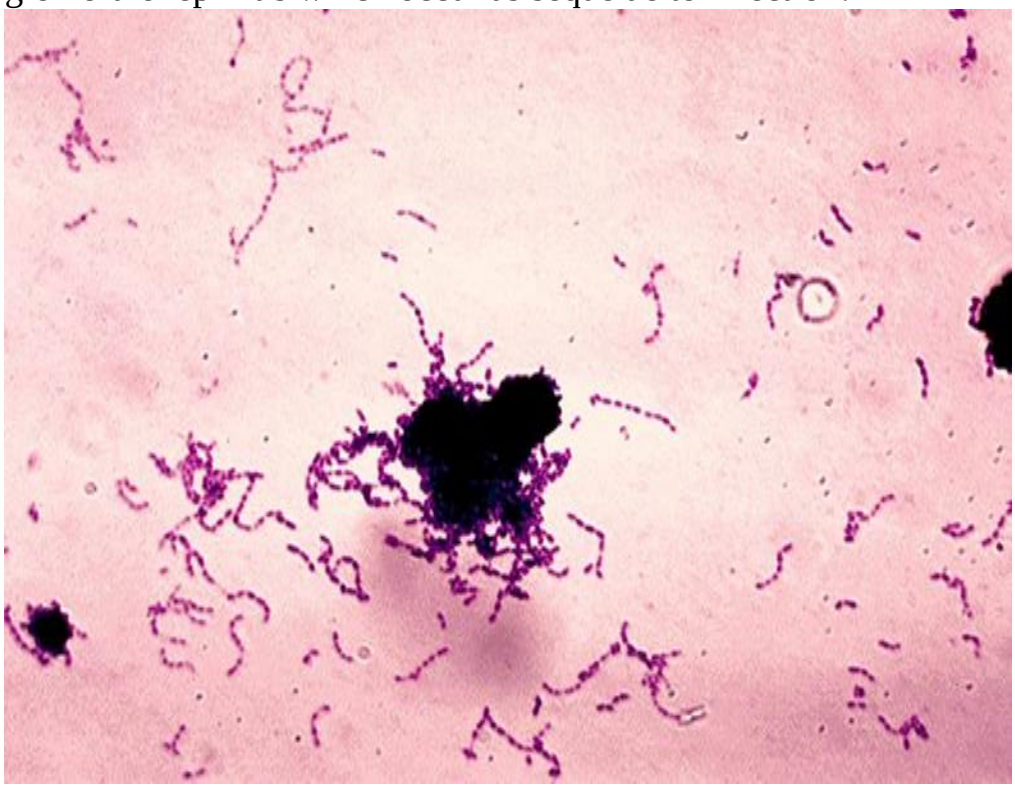
Petridish:these dishes (plates) used as container of culture media .Flasks ,cylinders ,tubes,pipettes.

STREPTOCOCCUS

INTRODUCTION

Streptococci

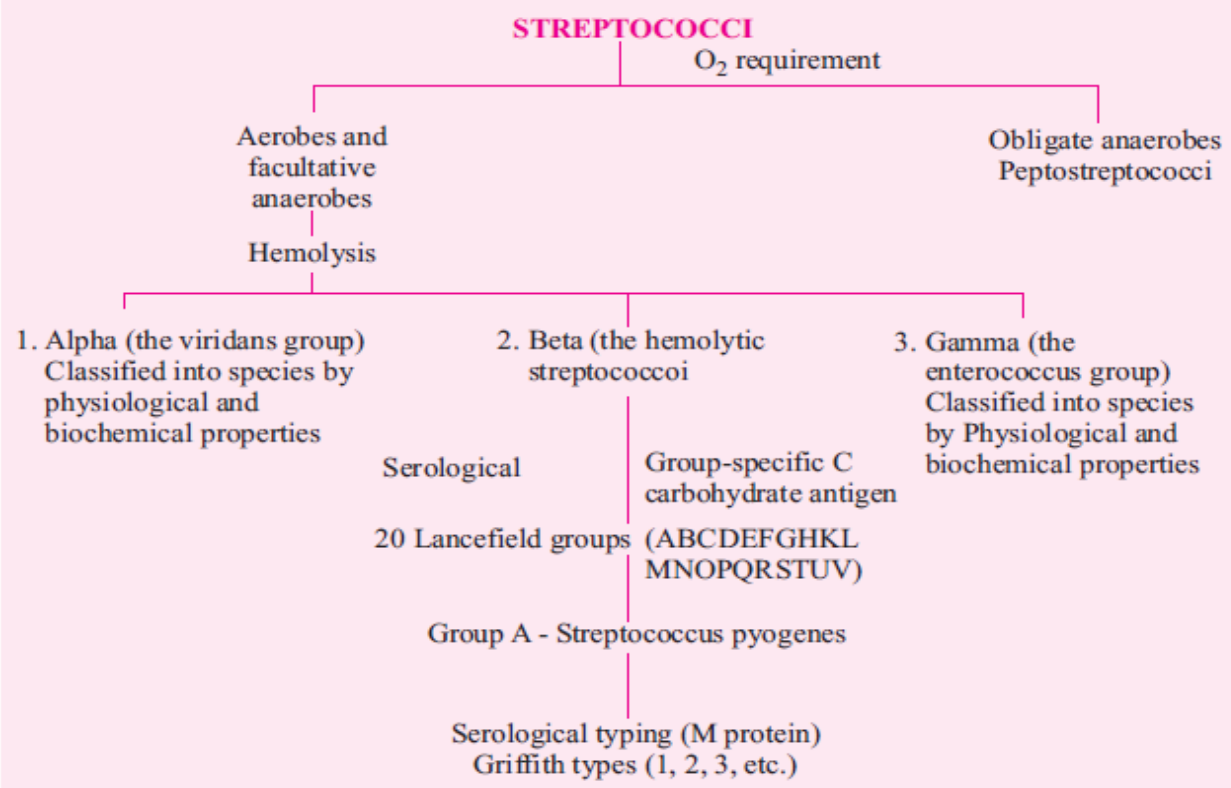
Streptococci are Gram-positive cocci arranged in chains or pairs. They are part of the normal flora of humans and animals. Some of them are human pathogens.The most important of them is *Streptococcus pyogenes* causing pyogenic infections, with a characteristic tendency to spread,as opposed to staphylococcal lesions, which are typically localized. It is also responsible for the nonsuppurative lesions, acute rheumatic fever and glomerulonephritis which occur as sequelae to infection.



CLASSIFICATION

Several systems of classification have been employed but in medical bacteriology the following method is useful.

Streptococci are first divided into obligate anaerobes and facultative anaerobes.The aerobic and facultative anaerobic streptococci are classified on the basis of their hemolytic properties. Brown categorized them into three varieties based on the growth in 5% horse blood agar pour plate cultures.



1. Alpha (α) hemolytic streptococci

Alpha (α) hemolytic streptococci produce a greenish discolouration with partial hemolysis around the colonies These are known as 'viridans streptococci' or Streptococcus viridians (from 'viridis' meaning green). The alpha streptococci are normal commensals in the throat, but may cause opportunist infections rarely. Pneumococcus (*Streptococcus pneumonia*) is also an alpha hemolytic.

2. Beta (β) hemolytic streptococci

Beta (β) hemolytic streptococci produce a sharply defined, clear, colourless zone of hemolysis within which red cells are completely lysed.. Most pathogenic streptococci belong to this group.

3. Gamma (γ) or nonhemolytic streptococci

Gamma (γ) or nonhemolytic streptococci produce no change in the medium'. They include the fecal streptococci (enterococci, Str faecalis) and related species. They are called the 'enterococcus group'. Hemolytic streptococci were classified by Lancefield serologically into groups based on the nature of a carbohydrate (C) antigen on the cell wall.The great majority of hemolytic streptococci that produce human infections belong to group A. Hemolytic streptococci of group A are known as *Streptococcus pyogenes*. These may be further subdivided into types based on the protein (M, T and R) antigens present on the cell surface. Table 1

shows the medically important streptococci and their chacteristics.

Species or Common name	**Lancefield group**	**Hemolysis**	**Habitat in human hosts**	**Laboratory tests**	**Common diseases caused**
Str. pyogenes	A	Beta	Throat, Skin	Bacitracin sensitive; PYR test positive; Ribose not fermented	URTI, Pyoderma, RF, Glomerulonephritis
Str. agalactiae	B	Beta	Female genital tract, rectum		Nenonatal meningitis, septicemia
Str. equisimilis	C	Beta	Throat		Pharyngitis, endocarditis
Str. anginosus	A,C,F,G Untypable	Beta (alpha, gamma)	Throat, colon, female genital tract		Pyogenic infections
Enterococcus sp (Str faecalis and other enteroccci) Nonenterococcal Group D species (str bovis)	D D	Gamma (alpha, Beta) Gamma Alpha (gamma)	Colon colon		UTI, endocardities suppurative infections Endocardities
Viridans streptococci (many species)	Not typed		Mouth, colon, female genital tract	Optochin resistant, species classsification	Endocarditis Str.) ;(sanguis dental

				biochemical properties	.caries (str (mutans

Streptococcus pyogenes

Morphology : are spherical and oval in shape. They are arranged in .Streptococcus are gram positive,non-motive, non-sporing and capsulated.

Culture Characteristics : It is an aerobes & facultative anaerobes growing best at 37°. It is exacting in nutritive requirements, growth occurring in media containing fermentable carbohydrate & enriched with blood & serum.. Strains with well marked capsules produce'mucoid' colonies.

Resistance : *Str*. *Pyogenes* is a delicate organism, easily destroyed by heat (54°C for 30 minutes). It dies in a few days in cultures, unless stored at a low temperature (4°C ,survive in dust for several weeks if protection from sunlight. It is rapidly inactivated by antiseptics

Toxins, Enzymes & other virulence factors : Streptococcus *pyogenes* produces several types of exotoxins & enzymes those act as virulence factors.Also young protein act as a virulence factor by inhibiting phagocytosis. The C polysaccharide has been shown to have a toxic effect on connective tissue in experimental animals.

Hemolysins : Streptococci produce two hemolysins, streploysin 'O and 'S'.

Streptolysin O is so called because it is **oxygen labile.** It is inactive in the oxidized form but may be reactivated by treatment with mild reducing agents. On blood agar, streptolysin O activity is seen only in pour plates and not in surface cultures. It may be obtained in the active state by growing streptococci in broth containing reducing agents such as sodium hydrosulphite. It is also heat labile. It appears to be important in contributing to virulence, lethal on intravenous injection into animals and has specific cardiotoxic activity., has leucotoxic activity also. In its biological action, streptolysin O resembles the oxygen labile hemolysins of Cl. *perfringens*, Cl. *tetani* and the *pneumococcus*. Streptolysin O is antigenic and antistreptolysin O appears in serum after streptococcal infection, which is very important in diagnosis.

Streptolysin S is so called because it is **soluble in serum**. It shows stability with oxygen, dry heat. It is responsible for hemolysis seen on the surface of the blood agar plates. It also has leucocidal activity. Pyrogenic exotoxin (erythrogenic)This toxin induces fever so named. It is a super

antigen so act as T-cell mitogens and causes rapid release of inflammatory cell which cause wide spread manifestation.

Streptokinase is an enzyme which acts as a toxin which promotes the lysis of human fibrin clot by activating plasminogen to plasmin. It act as a diagnostic marker. It shows biological significance during infection, by breaking down the fibrin barrier around tissue & thus helps in spread of infection. It shows therapeutic significance in myocardial infarction & other thromboembolic disorders.

Hyaluronidase : It is a enzyme which breaks down the hyaluronic acid of tissue. It is a biological significance it helps in spread of infection.

Cell Wall Components and Antigenic Structure

_ Group-specific carbohydrate

The cell wall contains a group-specific polysaccharide It is a polymer of *N*-acetylglucosamine and rhamnose. It is nontoxic

Type-specific proteins

The cell wall of *S. pyogenes* has three major proteins, M, T, and R proteins. These proteins are useful for serologic typing (Griffith typing) of *S. pyogenes*.

M protein: M protein is the most important protein. It is acid- and heat-stable and trypsin-sensitive. It is the chief virulence factor of the cocci. It inhibits phagocytosis and facilitates the attachment of cocci to epithelial cells.

.

T proteins: These are trypsin-resistant (T) proteins and are acid and heat labile.

R proteins: These are pepsin sensitive but trypsin resistant.

Other cell surface components

Peptidoglycan, lipoteichoic acid, and F proteins are other components of the cell wall of *S. pyogenes*. Peptidoglycan confers rigidity to the cell wall. It is also responsible for producing fever, dermal and cardiac necrosis in animals, and lysis of erythrocytes

Pathogenicity

Str. pyrogen produces pyrogenic infection that spread locally along with lymphatic & blood serum. They produce mainly two types of lesions.

Suppurative infection Respiratory Infection**,** Skin and soft tissue**,** Genital (puerperal sepsis)**,**Abscess in liver, lung.**,** Kidney and brain.

Non-suppurative Acute rheumatic fever**,** Acute glomerulonephritis**.**

Respiratory Infection: The primary site of invasion of the human body of *Str pyogenes* is the throat. Sore throat is the most common in the streptococcal diseases. It may be localized as tonsillitis it may involve the pharynx more diffusely (pharyngitis). Virulent group A streptococci adhere to the pharyngeal epithelium by means of lipoteichoic acid covering the surface pili. Tonsillitis is more common in older children and adults than in younger children, who commonly develop diffuse pharyngitis.

Chronic Tonsilitis

From the throat, streptococci may spread to the surrounding tissues, leading to suppurative complications such as otitis media, mastoidities, and Suppurative adenitis.

Skin and soft tissue infections

Str pyogenes causes a variety of suppurative infections of the skin, including infection of wounds or burns, with a predilection to produce lymphangitis and cellulitis. Infection of minor abrasions may at times lead to fatal septicemia. The two typical streptococcal infections of the skin are Erysipelas and Impetigo.in same area occurs in some person.

Genital Infections : Both aerobic & anerobic streptococci are normal inhabitants of female genital tract. They are important causative organism of puerperal sepsis.

Other suppurative infections *Str pyogenes* may cause abscesses in internal organs such as the brain, lungs, liver and kidneys, and also septicemia and
pyemia.

Nonsuppurative complications : *Str pyogenes* infections lead to two important non-suppurative sequelae – acute rheumatic fever and acute glomerulonephritis.

Laboratory diagnosis of streptococci : In acute infections, diagnosis is established by culture, while in the nonsuppurative complications, diagnosis is mainly based on the demonstration of antibodies.

OTHER HEMOLYTIC STREPTOCOCCI

Group B (Str. agalactiae):-It is single most cause of Neonatal meningitis

Group C: Streptococci of this group are mainly animal pathogen & divided into four species

Group F:-These group poorly on blood agar unless incubated under CO2 they have been called “minute streptococci”.

Group G:-These are commensals in the throats of human beings, monkeys or dogs. They may occasionally cause tonsillitis, endocarditis and urinary infections in human beings.

Group D:-They mainly of two types Entercocci (*E.faecalis*) & Non-enterococci (*Str. bovis*, *Str. equines*)

Entercocci shows Distinctive features is ability to grow in presence of 40% bile, 6.5% sodium chloride, At pH 9.6 & temperature 45ºC and in 0.1% methylene blue milk. *E faecalls* is most common species isolated from human. It mainly causes UTI, Wound infection & endocarditis.
Non-enterococci are inhibited by 6.5% sodium chloride & bile they case UTI & endocarditis.

THE VIRIDANS GROUP

This group, formerly called Streptococcus viridians, is a mixture of streptococci normally resident in the mouth and upper respiratory tract, and typically producing greening (alpha lysis) on blood sugar .Some of them may be non-lytic. They cannot be categorized under the Lancefield antigenic groups.
They are ordinarily nonpathogenic but can on occasion cause disease. In persons with preexisting cardiac lesions, they may cause bacterial endocarditis. Following tooth extraction or other dental procedures, they cause transient bacteremia and get implanted on damaged or prosthetic valves or in a congenitally diseased heart.

Str mutans .Important in the causation of dental caries. It breaks down dietary sucrose, producing acid and a tough adhesive dextran. The acid damages dentine and the dextrans bind together food debris, epithelial cells, mucus and bacteria to form dental plaques, which lead to caries. Conditions in the oral cavity are diverse and complex, frequently changing from one extreme to another. Thus, to survive in the oral cavity, *S. mutans* must tolerate rapidly harsh environmental fluctuations and exposure to various antimicrobial agents to survive.
Under special conditions, commensal streptococci can switch to opportunistic pathogens, initiating disease and damaging the host. Oral streptococci have both harmless and harmful bacteria.

Mutans streptococci are the most important bacteria associated with tooth decay. *S. mutans*, the microbial species most strongly associated with carious lesions, is naturally present in the human oral microbiota. The growth and metabolism of *S. mutans*,changes local environmental conditions (pH, coaggregation, and substrate availability), thereby enabling more fastidious organisms to further colonize after them, forming dental plaque. Along with *S. sobrinus*, *S. mutans* plays a major

role in tooth decay, metabolizing sucrose to lactic acid using the enzyme glucansucrase.

The acidic environment created in the mouth by this process is what causes the highly mineralized tooth enamel to be at risk to decay. *S. mutans* is one of a few specialized organisms equipped with receptors that improve adhesion to the surface of teeth. Sucrose is used by *S. mutans* to produce a sticky, extracellular, dextran-based polysaccharide that allows them to cohere, forming plaque. *S. mutans* produces dextran via the enzyme dextransucrase (a hexosyltransferase) using sucrose as a substrate in the following reaction:

n sucrose $\rightarrow$ $(\text{glucose})_n + n$ fructose

Sucrose is the only sugar that bacteria can use to form this sticky polysaccharide.

The combination of plaque and acid leads to dental decay. Due to the role *S. mutans* plays in tooth decay, many attempts have been made to create a vaccine for the organism. So far, such vaccines have not been successful in humans.

Streptococci represent 20% of the oral bacteria and actually determine the development of the biofilms.

S. mutans is often acquired in the oral cavity subsequent to tooth eruption, but has also been detected in the oral cavity of pre-dentate children. It is generally, but not exclusively, transmitted via vertical transmission from caregiver (generally the mother) to child.

S. mutans is implicated in the pathogenesis of certain cardiovascular diseases, and is the most prevalent bacterial species detected in extirpated heart valve tissues.

Prevention and treatment:-

Practice of good oral hygiene including daily brushing, flossing and the use of appropriate mouthwash can significantly reduce the number of oral bacteria and inhibit their proliferation. Oral bacteria often live in plaque, a kind of biofilm, hence mechanical removal of plaque is the most effective way of getting rid of harmful oral bacteria, as bacterial biofilms are notoriously resistant to antibiotics and antimicrobial rinses.

Antimicrobial agents used in dentistry:-

Fluoride has a direct inhibitory effect on the Enolase enzyme.

Chlorhexidine reduces populations of *S. mutans*, presumably by interfering with bacterial adherence.

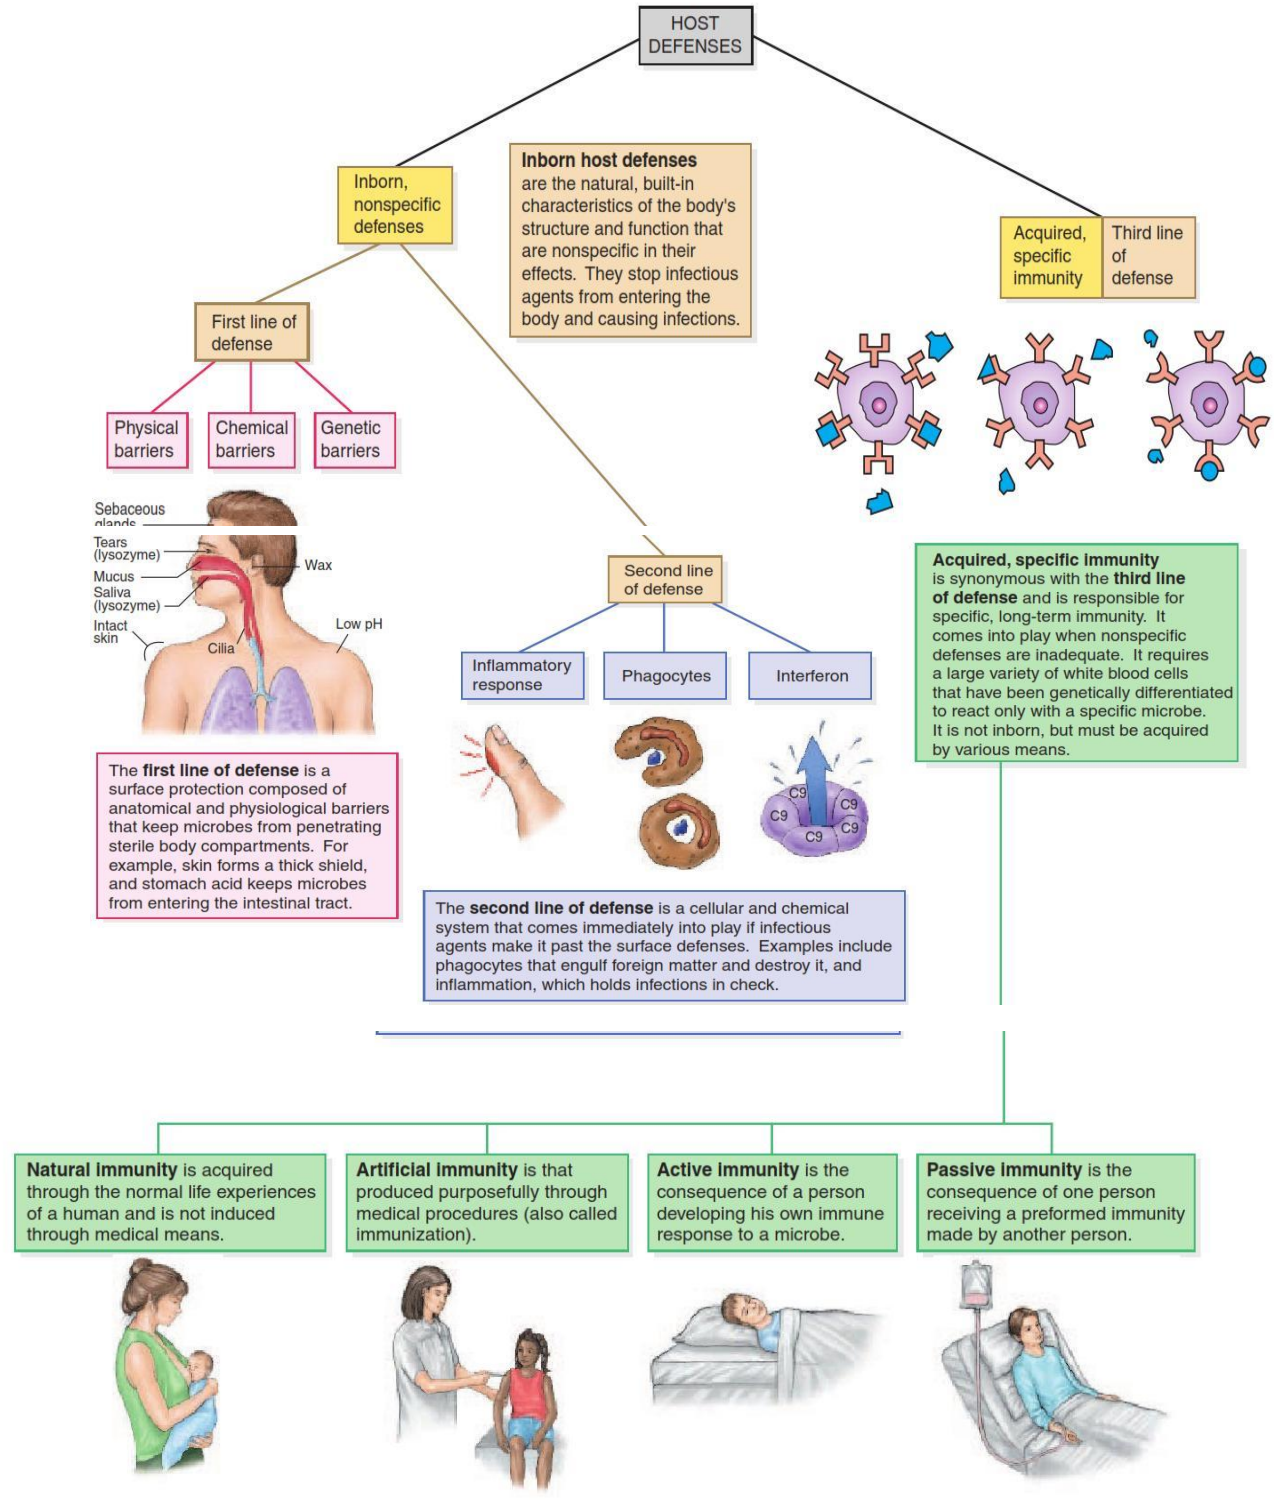
Xylitol is a noncariogenic sugar alcohol found in gum and oral health care products which is not able to be metabolized into the cariogenic acids that commonly cause tooth demineralization and decay

Immunity

The term immunity refers to the general ability of a host to resist a particular infection or disease.

Immunology is the science that is concerned with immune responses to foreign challenge and how these responses are used to resist infection. It includes the distinction between "self" and "nonself" and all the biological, chemical, and physical aspects of the immune response .There are two fundamentally different types of immune responses to an invading microorganism and/or foreign material.

1. The **nonspecific immune response** is also known as **nonspecific resistance** and **innate** or **natural immunity;** it offers resistance to any microorganism or foreign material encountered by the vertebrate host. It includes general mechanisms inherited as part of the innate structure and function of each animal (such as skin, mucus, and constitutively produced antimicrobial mediators like lysozyme), and acts as a first line of defense. The nonspecific immune response defends against foreign particles equally and lacks immunological memory that is, nonspecific responses occur to the same extent each time a microorganism or foreign body is encountered.



HOST DEFENSES
Inborn, nonspecific defenses
Inborn host defenses are the natural, built-in characteristics of the body's structure and function that are nonspecific in their effects. They stop infectious agents from entering the body and causing infections.
Acquired, specific immunity
Third line of defense
First line of defense
Physical barriers
Chemical barriers
Genetic barriers
Sebaceous glands
Tears (lysozyme)
Mucus
Saliva (lysozyme)
Intact skin
Wax
Cilia
Low pH
The first line of defense is a surface protection composed of anatomical and physiological barriers that keep microbes from penetrating sterile body compartments. For example, skin forms a thick shield, and stomach acid keeps microbes from entering the intestinal tract.
Second line of defense
Inflammatory response
Phagocytes
Interferon
C9
The second line of defense is a cellular and chemical system that comes immediately into play if infectious agents make it past the surface defenses. Examples include phagocytes that engulf foreign matter and destroy it, and inflammation, which holds infections in check.
Acquired, specific immunity is synonymous with the third line of defense and is responsible for specific, long-term immunity. It comes into play when nonspecific defenses are inadequate. It requires a large variety of white blood cells that have been genetically differentiated to react only with a specific microbe. It is not inborn, but must be acquired by various means.
Natural immunity is acquired through the normal life experiences of a human and is not induced through medical means.
Artificial immunity is that produced purposefully through medical procedures (also called immunization).
Active immunity is the consequence of a person developing his own immune response to a microbe.
Passive immunity is the consequence of one person receiving a preformed immunity made by another person.

First line of Defense

A- PHYSICAL BARRIERS IN NONSPECIFIC (INNATE) RESISTANCE

Skin

The intact skin contributes greatly to nonspecific host resistance .It forms a very effective mechanical barrier to microbial invasion. Its outer layer consists of thick, closely packed cells called keratinocytes, which produce keratins. Keratins are scleroproteins (i.e., insoluble proteins) that make up the main components of hair, nails, and the outer skin cells. These outer skin cells shed continuously, removing any grime or microorganisms that manage to adhere to their surface. The skin is slightly acidic (around pH 5 to 6) due to skin oil, secretions from sweat glands, and organic acids produced by commensal staphylococci. It also contains a high concentration of sodium chloride and is subject to periodic drying.

Mucous Membranes

The mucous membranes of the eye (conjunctiva) and the respiratory, digestive, and urogenital systems withstand microbial invasion because the intact stratified squamous epithelium and mucous secretions form a protective covering that resists penetration and traps many microorganisms. This mechanism contributes to nonspecific immunity.

Respiratory System

The mammalian respiratory system has formidable defense mechanisms. The average person inhales at least eight microorganisms a minute, or 10,000 each day. Once inhaled, a microorganism must first survive and penetrate the air-filtration system of the upper and lower respiratory tracts.

Gastrointestinal Tract

Most microorganisms that reach the stomach are killed by gastric juice (a mixture of hydrochloric acid, proteolytic enzymes, and mucus). The very acidic gastric juice (pH 2 to 3) is sufficient to destroy most organisms and their toxins, although exceptions exist (protozoan cysts, Helicobacter pylori, Clostridium and Staphylococcus toxins).

The Eye

The conjunctiva is a specialized, mucus-secreting epithelial membrane that lines the interior surface of each eyelid and the exposed surface of the eyeball. It is kept moist by the continuous flushing action of tears (lacrimal fluid) from the lacrimal glands.Tears contain large amounts of lysozyme, lactoferrin, and sIgA and thus provide chemical as well as physical protection.

B- CHEMICAL MEDIATORS IN NONSPECIFIC (INNATE) RESISTANCE

-Antimicrobial Peptides

-Bacteriocins

Second line of Defense

A- Complement system

B- Cytokines

Defense against viruses, microorganisms and their products, parasites, and cancer cells is mediated by both nonspecific immunity and specific immunity. Cytokines are required for immune regulation of both of these immune responses. The term cytokine is a generic term for any soluble protein or glycoprotein released by one cell population that acts as an intercellular (between cells) mediator or signaling molecule. When released from mononuclear phagocytes, these proteins are called monokines; when released from T lymphocytes they are called lymphokines; when produced by a leukocyte and the action is on another leukocyte, they are interleukins; and if their effect is to stimulate the growth and differentiation of immature leukocytes in the bone marrow, they are called colony-stimulating factors (CSFs).

c-Interferons(IFNs) are a group of related low molecular weight, regulatory cytokines produced by certain eukaryotic cells in response to a viral

infection. Besides defending against viruses, they also help regulate the immune response.

d-PHAGOCYTOSIS

e-INFLAMMATION

Third line of Defense

2. **The specific immune responses, also known as acquired**, adaptive, or specific immunity, resist a particular foreign agent, which occurs after exposure to an antigen (eg, an infectious agent) is specific and is mediated by either antibody or lymphoid cells. It can be passive or active.

- **Passive Immunity**

Passive immunity occurs naturally during pregnancy; the mother's IgG antibodies cross the placenta and protect the fetus. These antibodies remain active in the newborn infant during the first few months of life, when the neonate's own immune responses are still developing. Consequently, a number of infectious diseases normally do not occur until a baby is three to six months of age, by which time the maternal antibodies have been degraded. Passive immunity also occurs as a result of breast feeding; the IgA in breast milk protects the alimentary tract of the child. Passive immunity provides no memory; once the transferred antibodies are degraded, the protection is lost.

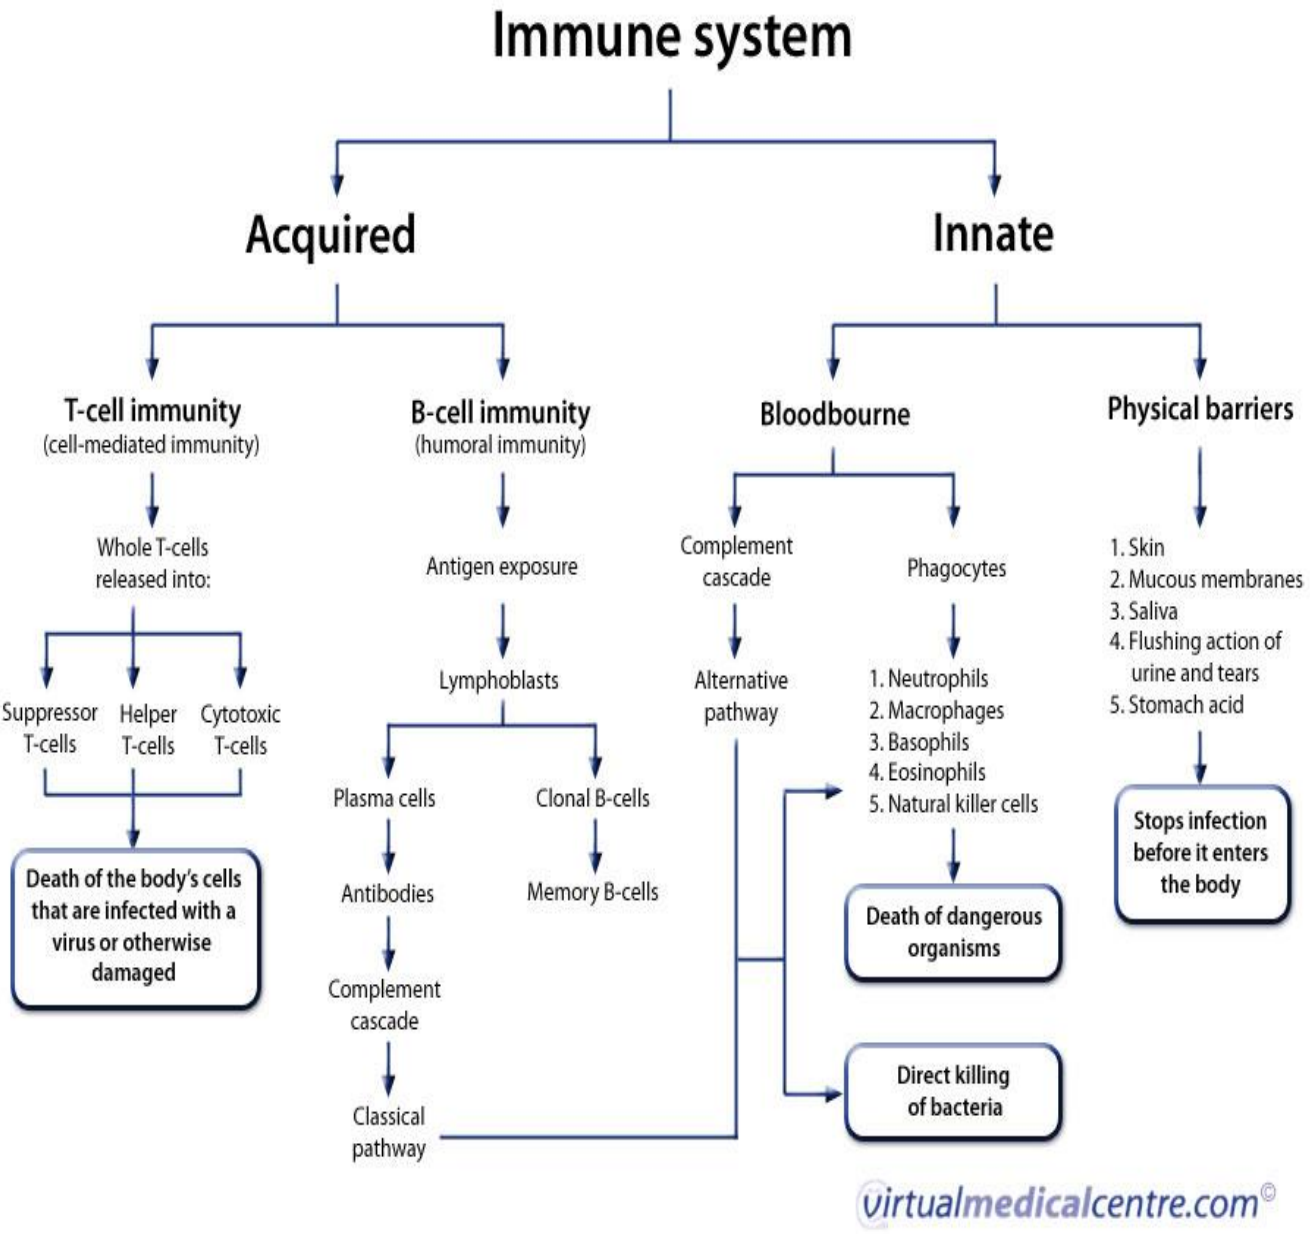
Artificial passive immunity involves transferring antibodies

produced by other people or animals. This type of immunity can be used to prevent disease before or after likely exposure to an infectious agent, to limit the duration of certain diseases, and to block the action of microbial toxins. An antibody preparation that protects against a given toxin is called an antitoxin.

Active Immunity

Active immunity is the result of an immune response in an individual upon exposure to antigen. Specific B and T lymphocytes are activated and then proliferate, providing the individual with the lasting protection associated with immunological memory. Active immunity can develop either naturally from an actual infection or artificially from administration of a vaccine.

	Active	Passive
Natural	Natural exposure to antigen induces an immune response; immunity following an attack of measles.	Transfer of antibodies or cells produced by others; temporary immunity from antibodies of the mother transferred to infant across the placenta or in milk.
Artificial	Deliberate exposure to antigen induces an immune response; immunization of children.	Antibodies in immune serum are introduced into body; injection of rabies immune globulin after a dog bite.



Cells of the Immune System

The cells responsible for both nonspecific and specific immunity are the leukocytes. All leukocytes originate from stem cells in the fetal liver and in the bone marrow of the animal host. stem cells have not yet committed to differentiating into one specific cell type. When they migrate to other body sites, some differentiate into hematopoietic stem cells that are destined to become blood cells.

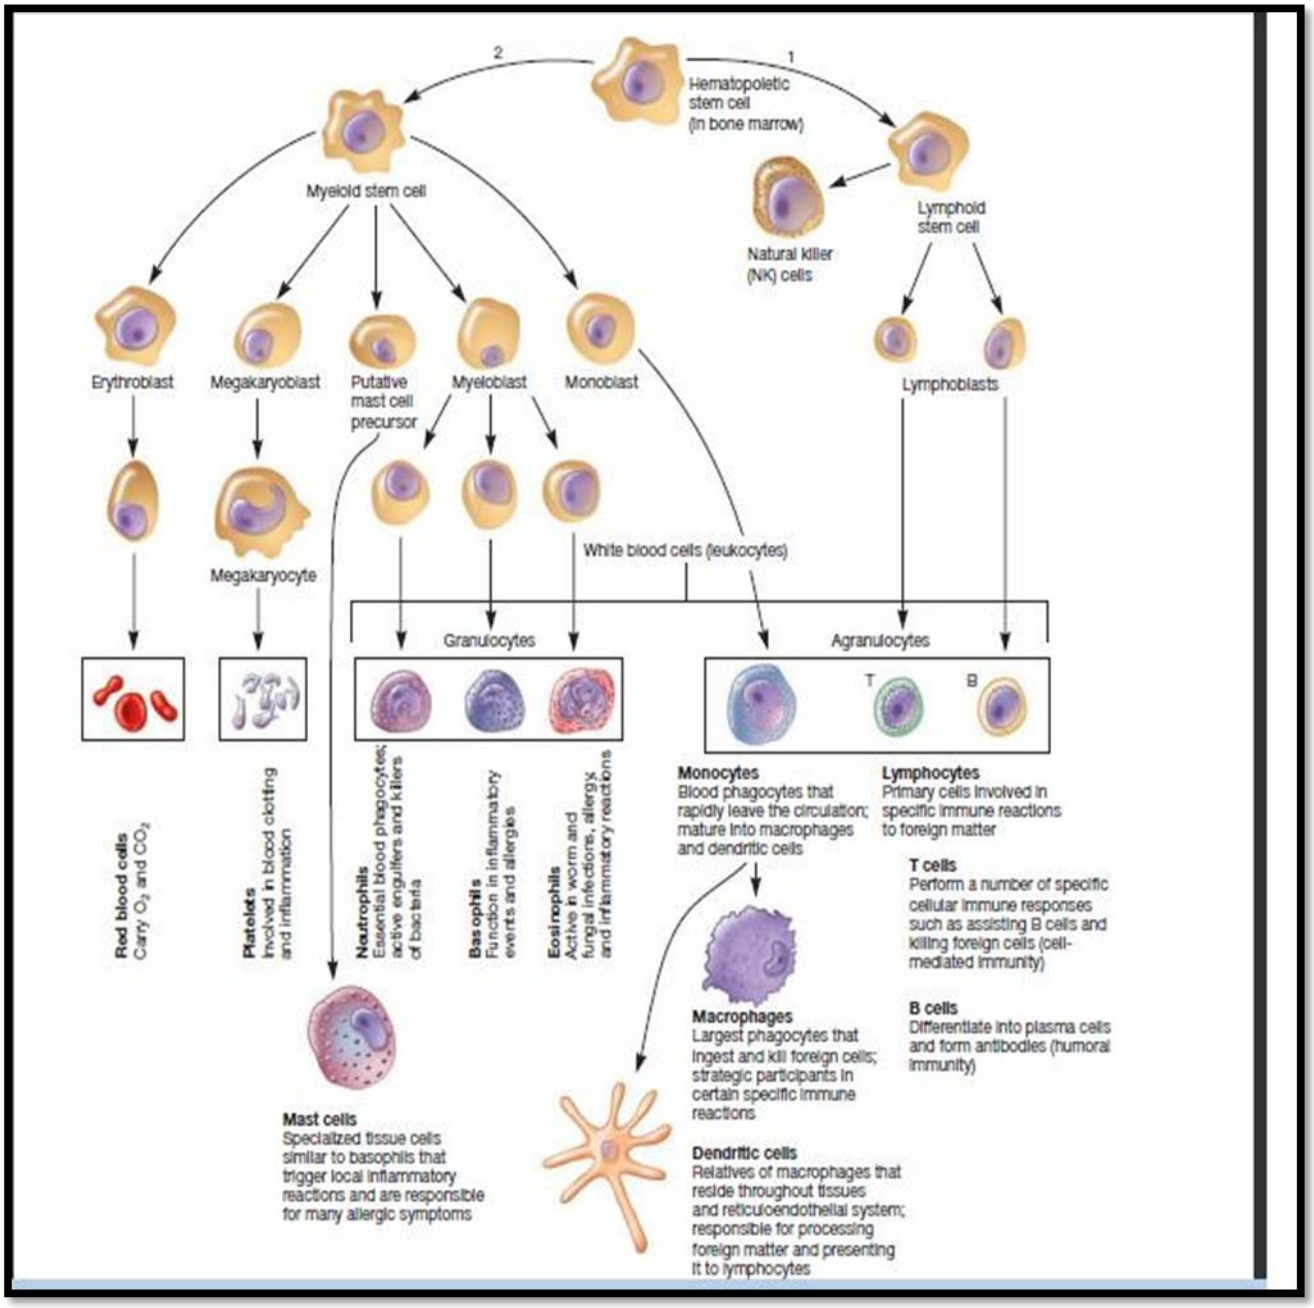
When stimulated to undergo further development, some leukocytes become residents within tissues, where they respond to local trauma. These cells may sound the alarm that signals invasion by foreign organisms. Other leukocytes circulate in body fluids and are recruited to the sites of infection after the alarm has been raised. The average adult has approximately 7,400 leukocytes per cubic millimeter of blood

Normal Adult Blood Count

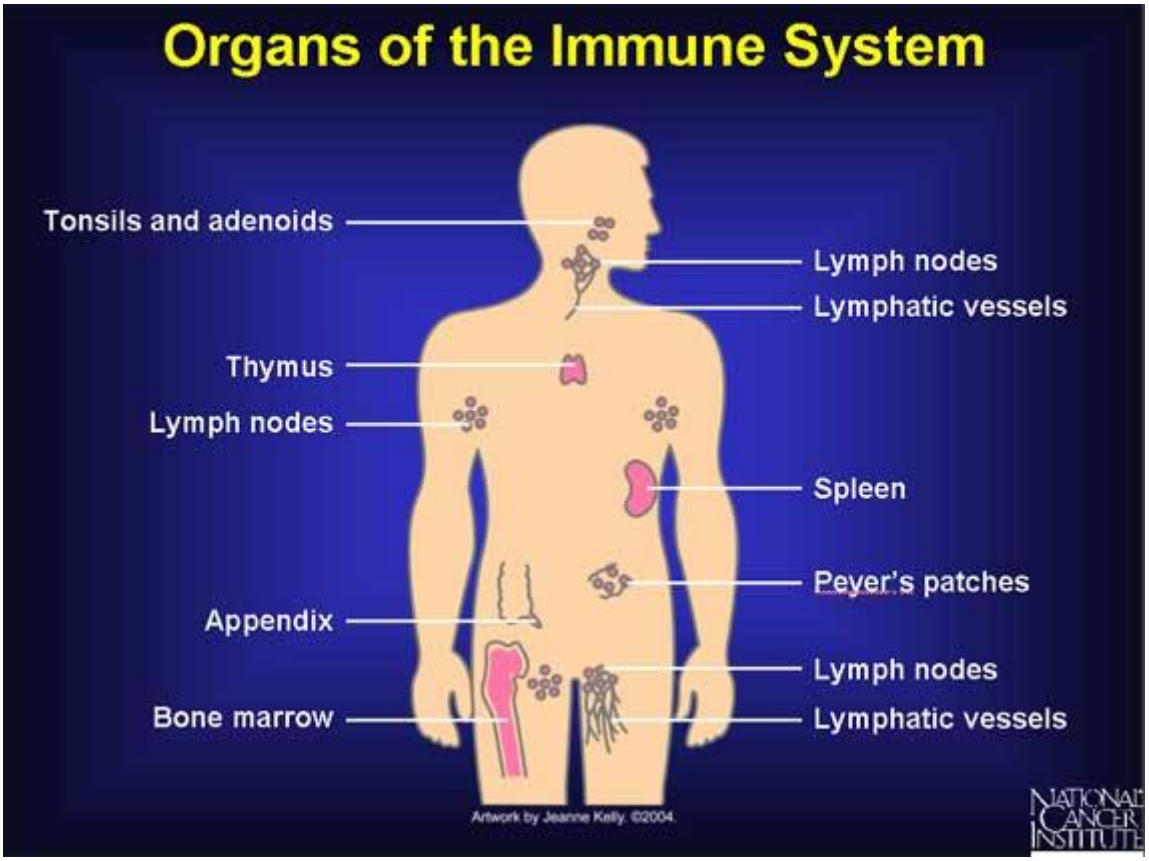
Cell Type	Cells/mm^3	Percent WBC
Red blood cells	5,000,000	
Platelets	250,000	
White blood cells	7,400	100
Neutrophils	4,320	60
Lymphocytes	2,160	30
Monocytes	430	6
Eosinophils	215	3
Basophils	70	1

This average value shifts substantially during an immune response. In defending the host against pathogenic microorganisms, leukocytes cooperate with each other first to recognize the pathogen as an invader and then to destroy it. These different leukocytes are now briefly examined.

Granulocytes: Granulocytes have irregularly shaped nuclei with two to five lobes. Their cytoplasm has granules that contain reactive substances that kill microorganisms and enhance inflammation.

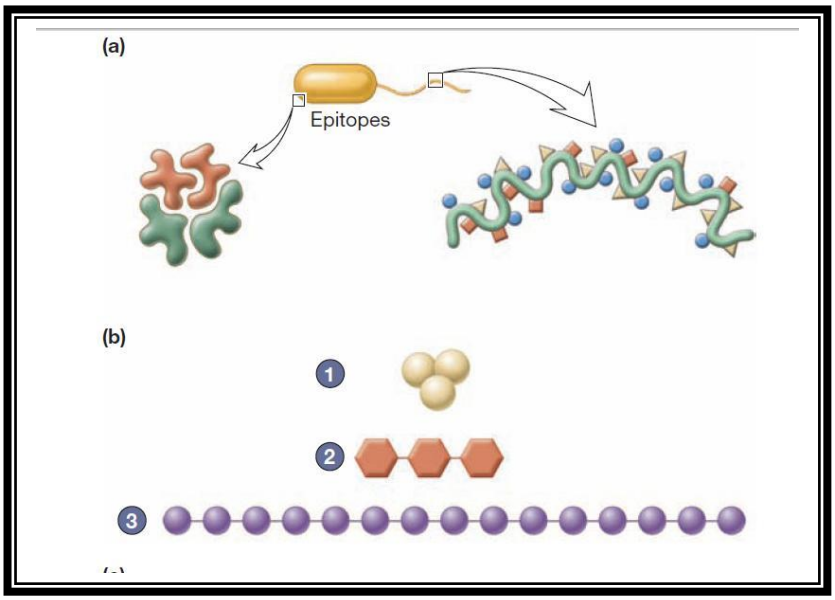


Three types of granulocytes exist: basophils, eosinophils, and neutrophils. Because of the irregularly shaped nuclei , neutrophils are also called polymorphonuclear neutrophils,or PMNs .



ANTIGENS

The immune system distinguishes between "self" and "nonself" through an elaborate recognition process. Self and nonself substances that elicit an immune response and react with the products of that response are often called antigens. Antigens include molecules such as proteins, nucleoproteins, polysaccharides, and some glycolipids. While the term "immunogen" (immunity generator) is a more precise descriptor for a substance that elicits a specific immune response, "antigen" is used more frequently. Most antigens are large, complex molecules with a molecular weight generally greater than 10,000 Daltons (Da). The ability of a molecule to function as an antigen depends on its size, structural complexity, chemical nature, and degree of foreignness to the host. Each antigen can have several antigenic determinant sites, or epitopes .



a- Complex molecules with several epitopes make good immunogens.

b- Poor immunogens include small molecules not attached to a carrier molecule (*1*), simple molecules (*2*), and (*3*) large but repetitive molecules.

Epitopes are the regions or sites in the antigen that bind to a specific antibody or T-cell receptor through an antigen-binding site.

Haptens

Many small organic molecules are not antigenic by themselves but become antigenic if they bond to a larger carrier molecule such as a protein. These small antigens are called haptens . When lymphocytes are stimulated by the combined hapten-carrier molecule, they can react to either the hapten or the larger carrier molecule. This occurs because the hapten functions as one epitope of the carrier. When the carrier is processed and presented to T cells, responses to both the hapten and the carrier protein can be elicited. As a result, both hapten specific and carrier-specific antibodies can be made. One example of a hapten is penicillin. By itself penicillin is a small molecule and is not antigenic. However, when it is combined with certain serum proteins of sensitive individuals, the resulting molecule becomes immunogenic, activates lymphocytes, and initiates a severe and sometimes fatal allergic immune reaction. In these instances the hapten is acting as an antigenic determinant on the carrier molecule.

ANTIBODIES

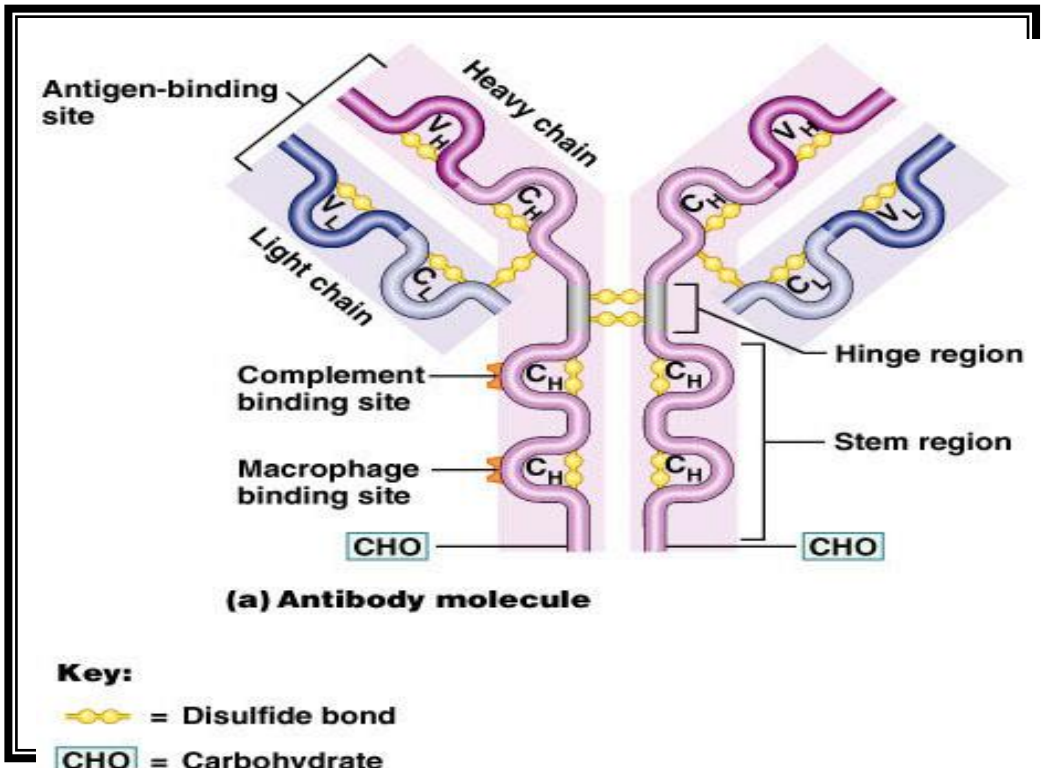
Antibodies are glycoprotein molecules also called immunoglobulins. Each antibody has at least two sites that bind to antigenic determinants. These sites are known as antigen binding sites.The number of antigen binding sites on an antibody

determines the valance of that antibody. Most human antibodies have two binding sites, therefore, they are bivalent.

BASIC ANTIBODY STRUCTURE

1- Consists of four looping polypeptide chains linked together with disulfide bonds. Two identical heavy (H) chains and two identical light (L) chains.

2. The four chains bound together using disulfide bonds to form an antibody monomer which is "Y" shaped.



3. Each chain has a variable (V) region at one end and a constant (C) region at the other end.

4. Both the H and L chains have sections located at the ends of the Y's arms, called (V) regions.

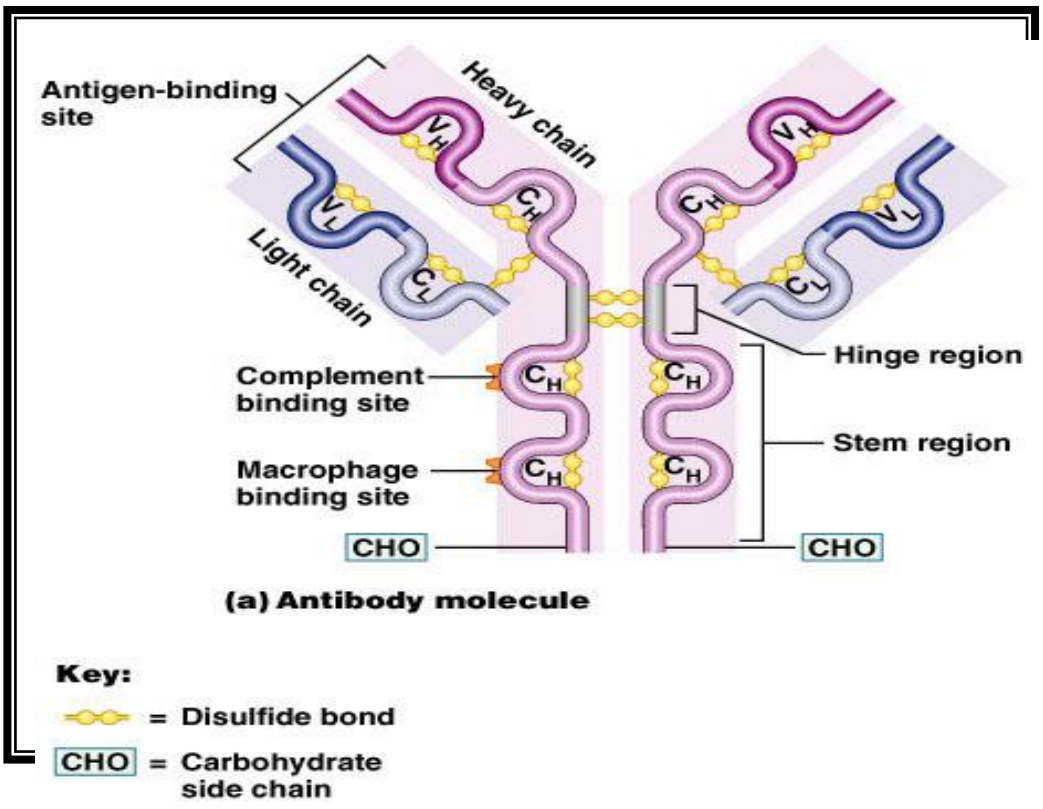
5. Variable regions of the heavy and light chains combine to form the antigen-binding site.

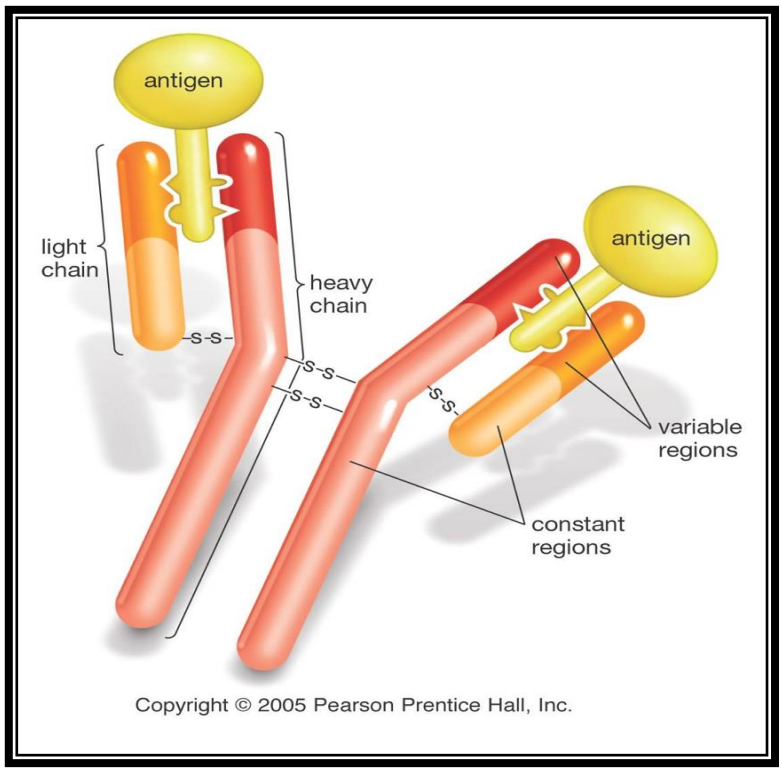
6. The stem of the antibody monomer and lower parts of the Y's arms are called constant (C) regions.

7.There are 5 major sequences found for C regions of H chains, and there are 2 different sequences for L chains.

8.Each H chain sequence determines a different class of immunoglobulin.

9.The stem of the Y shaped antibody monomer is called the Fc





These names were assigned following early studies that showed that enzymatic digestion of antibodies yielded two types of fragments— fragments that were antigen-binding (Fab) and fragments that could be crystallized (Fc).

There are five major classes of human immunglobulin (Ig) molecules IgM, IgG, IgA, IgD, and IgE. Each class shares the same basic monomeric structure, but is distinguished by a characteristic amino acid sequence in the constant portion of the heavy chain. Since this is the part of the molecule that interacts with other "players" of the immune system, the various classes differ in their functional properties. The specialized attributes of each class will

be described later, after we consider some of the general characteristics of antibodies.

IgG

1. This monomer is the most abundant and diverse accounts for about 80-85% of all antibodies.
2. These monomers can crosses the placenta and confers passive immunity, as well as, blood vessels.
3. Monomers activate complement and increase phagocytosis.
4. These monomers convey long term immunity
5. IgG protect against circulating bacteria and viruses, and bacterial toxins.

IgM

1. This monomer comprises about 5-10% of the antibodies in serum.
2. IgM are the first ones to appear in response to the initial exposure to an antigen.
3. IgM have a pentamer structure.
4. They large size prevent IgM from moving about as freely as IgG, therefore, they remain in the blood vessels.
5. They fix complement.

IgA

1. This monomer accounts for about 15% of the antibodies in serum.
2. IgA can be monomers or dimers.

3. IgA monomers are found in salvia, sweat, breast milk, and secretions of the G.I. tract.
4. They do not fix complement
5. The main function of IgA is to prevent the attachment of pathogens to mucosal surfaces.

IgD

1. IgD atibodies comprise only about 0.2% of the total serum antibodies.
2. IgD antibodies are found in blood and lymph and on the surfaces of B cells.
3. They do not fix complement.
4. They help to initiate the immune response.

IgE

1. IgE antibodies comprise about 0.002% of the total number of antibodies.
2. IgE molecules bind tightly by their Fc ends to receptors on mast cells and basophils. This causes the release of histamine.
3. They do not fix complement.

regulated; each lymphocyte, the primary participants in the

adaptive response, requires a "second opinion" from a different type of cell before it can unleash its power.

Humoral immunity is mediated by B lymphocytes, or B cells.

B cells develop in the bone marrow. In response to extracellular antigens, B cells may be triggered to proliferate and then differentiate into plasma cells, which function as factories that produce Y-shaped molecules called antibodies. These molecules bind to antigens, providing protection to the host by mechanisms that will be described shortly. A high degree of specificity is involved in the binding, so a multitude of different antibody molecules are needed to bind to the wide array of antigens that are encountered throughout life. Some of the B cells form memory cells, long-lived cells that respond more quickly if the antigen is encountered again.

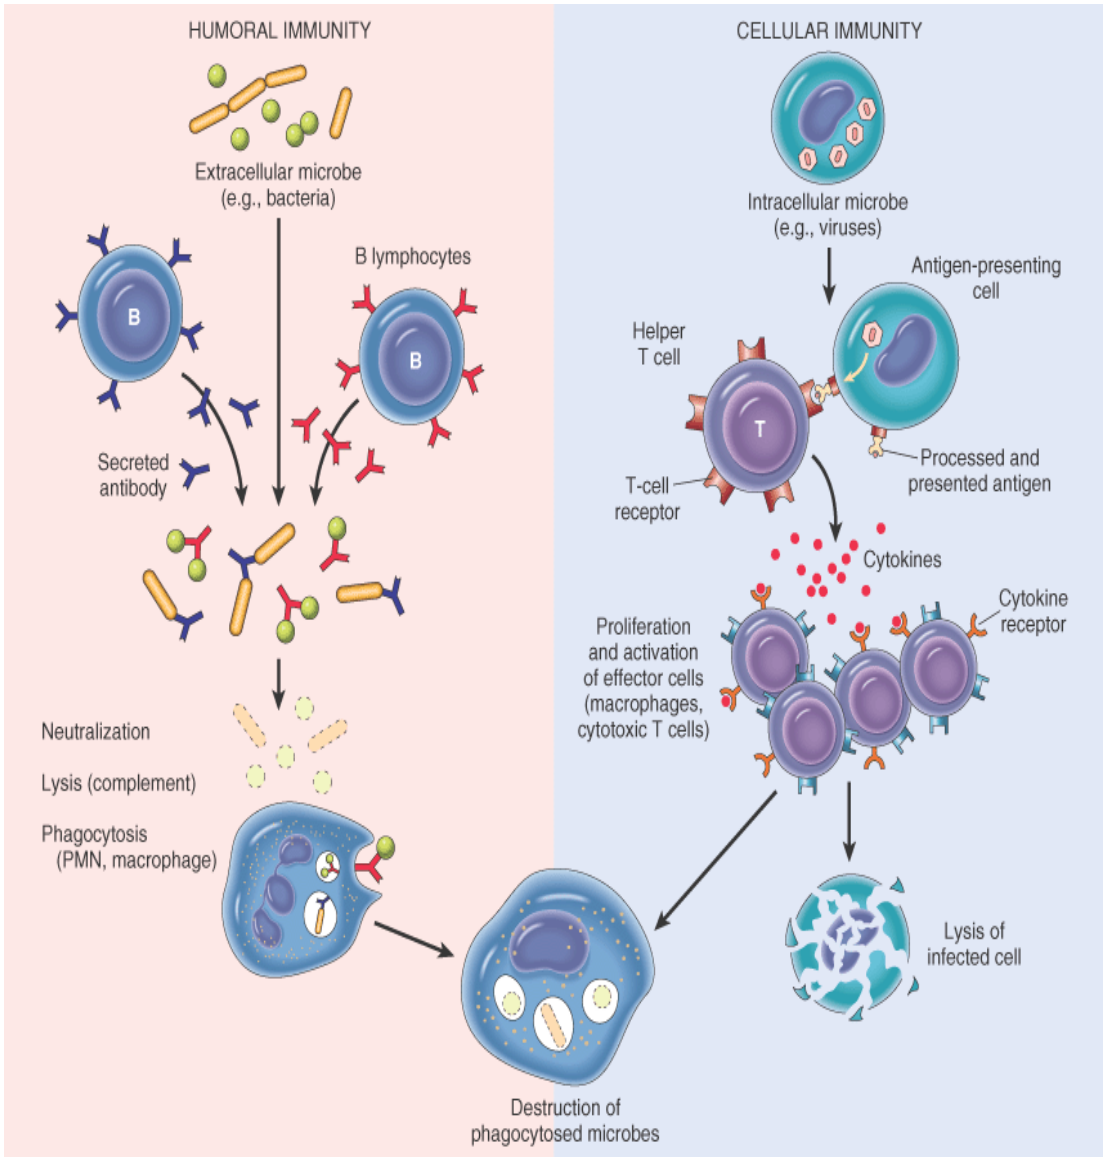
Antibody molecules have two functional regions the two identical arms and the stem of the molecule. It is the arms of the Y that bind to a specific antigen; the amino acid sequence of the end of the arms varies from antibody to antibody, providing the basis for their specificity. The stem of the Y functions tagging antigen bound by antibody and enlisting other components of the immune system to eliminate the bound molecule.

Antibodies that bind to an antigen protect the host by both direct and indirect mechanisms. Simply by coating an antigen, the

antibodies prevent that molecule from binding to critical sites on host cells. For example, a viral particle that has been coated with antibody cannot bind to its intended receptor on a host cell and, therefore, because it cannot attach, it is unable to enter the cell. The indirect protective effect is due to the "red flag" region that facilitates elimination of the antigen by the innate defenses. Phagocytes, for example, have receptors for that region of the antibody molecule, enabling them to more easily engulf an antigen coated with bound antibodies; this is the process of opsonization.

How does a B cell know when to replicate in order to eventually produce antibodies?

Each B cell carries on its surface multiple copies of a membrane bound derivative of the antibody it is programmed to make each of these molecules is called a B-cell receptor. If the B cell encounters an antigen that its B-cell receptors bind, then the cell may gain the capacity to multiply. Clones, or copies, of the cell are produced that can eventually differentiate to become plasma cells that make and secrete copious amounts of antibody. Generally, however, before the B cell can multiply, it needs confirmation by another lymphocyte, an effector T-helper cell, that the antigen is indeed dangerous.



PRIMARY and SECONDARY INFECTION

1. Primary response – after first exposure to an Ag immune system produces IgM and a gradual increase in Ab titer.

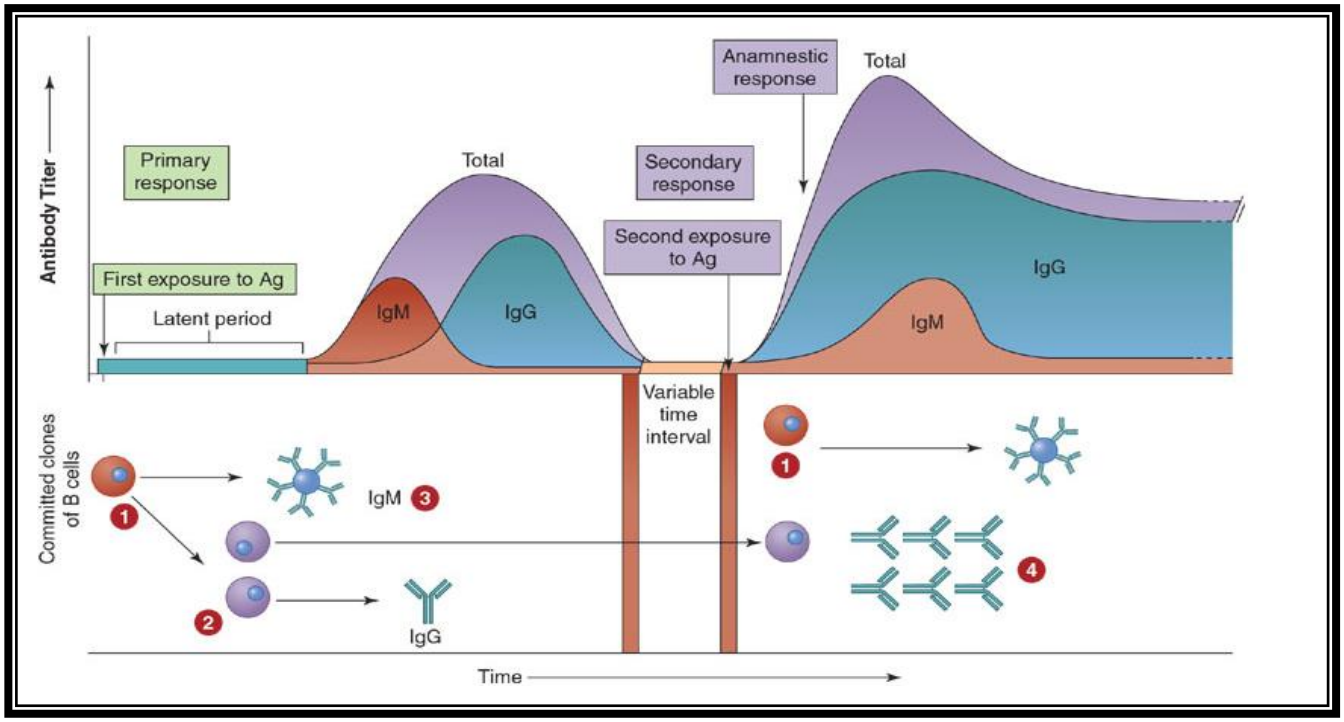
2. Secondary response –after second contact with the same Ag, immune system produces a more rapid, stronger response due to memory cells.

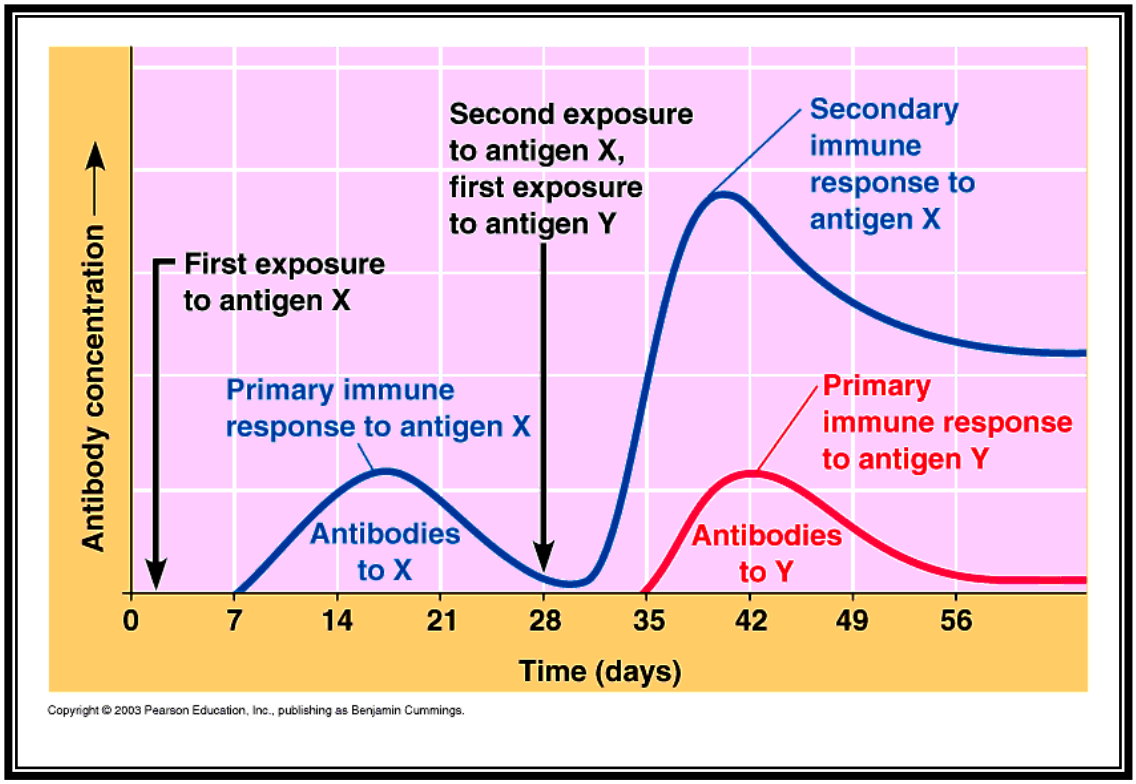
Antibody production occurs in four phases following antigen challenge:

- Lag phase when no antibody is detectable.
- Log phase in which antibody titer rises logarithmically.
- Plateau phase during which the antibody titer remains steady.
- Decline phase during which antibody levels gradually decline

■ You must be able to differentiate a primary and secondary immune response based on the following:

- ❑ **Time**
- ❑ **Antibody Titer**
- ❑ **Antibody Class**
- ❑ **Antibody affinity and avidity**





Elaborate Immunogenicity

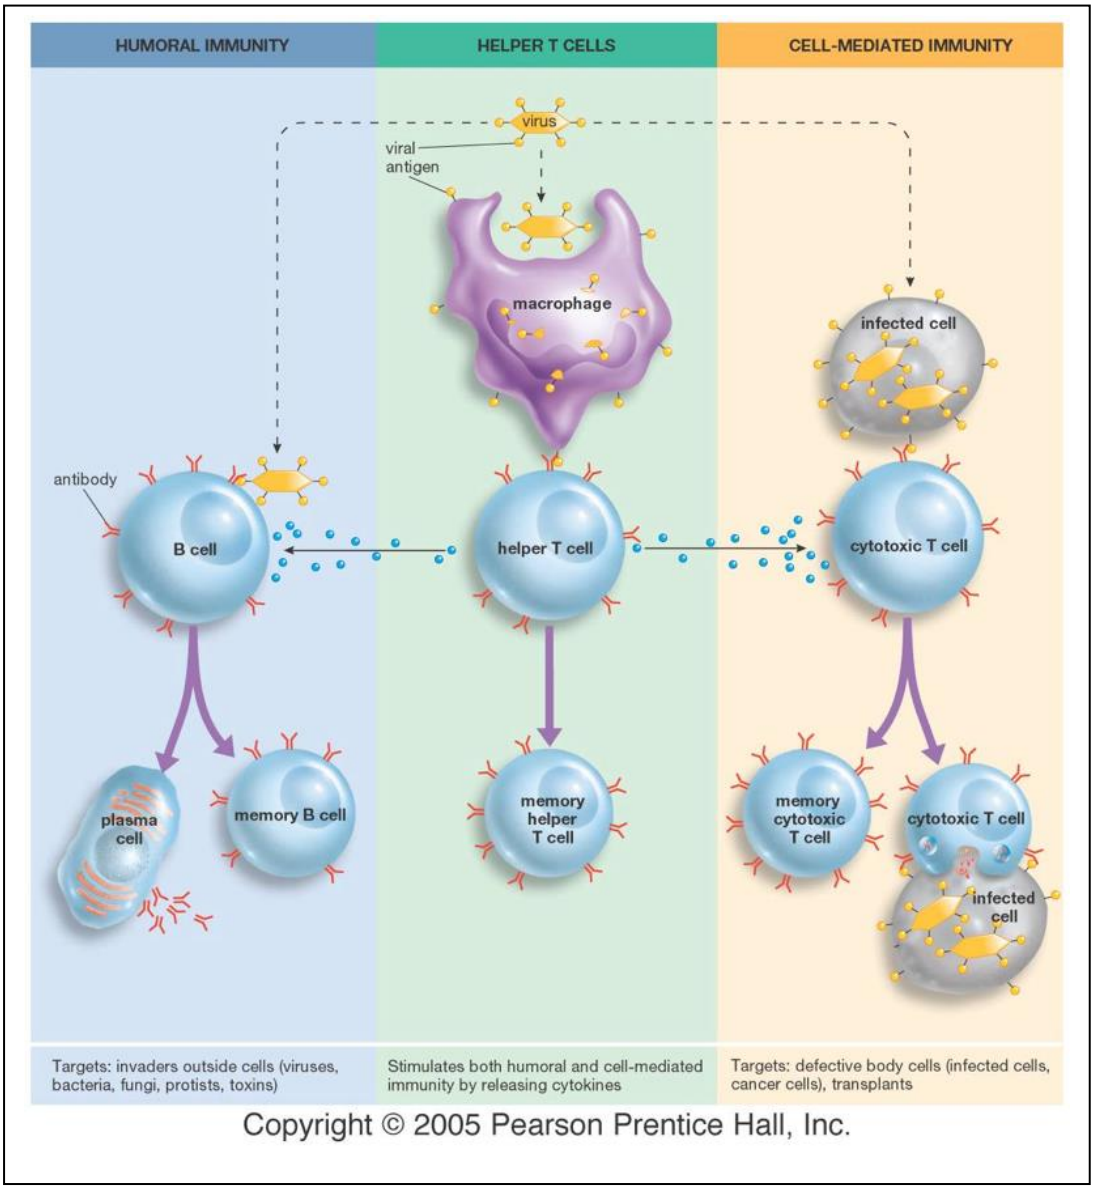
Ability to induce humoral and/or cell-mediated immune response" B cells + Antigen □ Plasma cells + Memory Cells

T cells + Antigen + MHC □ T effector cells + Memory Cells

Antigenicity

Ability to combine specifically with the final product of the above responses" (i.e antibodies and/or cell surface receptors)

Example: Haptens = molecules that can bind to antibodies or surface receptors (antigenic). However, they cannot induce specific immune response alone (non immunogenic)



The immune system is a myriad of cells, tissues, and soluble factors that cooperate to defend against foreign invaders.

antibody (immunoglobulin) A glycoprotein made by plasma cells (mature B cells) in response to the introduction of an antigen. The antibody-binding region of an antibody molecule assumes a fi nal confi guration that is the three-dimensional mirror image of the antigen that stimulated its synthesis. Thus the antibody can bind to the antigen with exact specifi city.

antigen A foreign substance (such as a protein, nucleoprotein, polysaccharide, or sometimes a glycolipid) that induces an immune response.

basophil A white blood cell in the granulocyte lineage that is weakly phagocytic. Importantly, it synthesizes and stores vasoactive molecules (e.g., histamine) that are released in response to external triggers.

B lymphocyte or **B cell** A type of lymphocyte derived from bone marrow stem cells that matures into an immunologically competent cell. Following interaction with an antigen, it becomes a **plasma cell,** which synthesizes and secretes antibodies.

chemokine A glycoprotein having potent leukocyte activation and chemotactic activity.

complement system Plasma proteins that bind to foreign materials to remove them from the host.

cytokine A general term for proteins released by cells of the immune system in response to specifi c stimuli. Cytokines infl uence the activities of other cells.

dendritic cell An antigen-presenting cell that has long membrane extensions resembling the dendrites of neurons. These cells are found in the lymph nodes, spleen, and thymus (interdigitating dendritic cells); skin (Langerhans cells); and other tissues (interstitial dendritic cells).

interferon (IFN) A glycoprotein that has nonspecifi c antiviral activity by stimulating cells to produce antiviral proteins, which inhibit the synthesis of viral RNA and proteins. Interferons also regulate the growth, differentiation, and function of a variety of immune system cells.

interleukin A cytokine produced by macrophages and T cells that regulates cellular growth and differentiation, particularly of lymphocytes.

lymph node A small secondary lymphoid organ that contains lymphocytes, macrophages, and dendritic cells. It serves as a site for fi ltration and removal of foreign antigens and for the activation and proliferation of lymphocytes.

lymphokine A biologically active glycoprotein secreted by activated lymphocytes, especially sensitized T cells. It acts as an intercellular mediator of the immune response and transmits signals affecting cell growth, differentiation, and behavior.

macrophage A large, mononuclear phagocytic cell, present in various tissues. Macrophages are derived from **monocytes.** They phagocytose and destroy pathogens; macrophages also activate B cells and T cells.

membrane attack complex (MAC) Complement components (C5b–C9) that assemble to create a pore in the plasma membrane of a target cell, leading to target cell lysis.

monocyte-macrophage system The collection of fi xed phagocytic cells (including macrophages, monocytes, and specialized endothelial cells) located in the liver, spleen, lymph nodes, and bone marrow. This system is an important component of the host's nonspecifi c defense against pathogens.

monokine A protein (cytokine) produced by mononuclear phagocytes (monocytes or macrophages) that mediates immune responses.

natural killer (NK) cell A type of white blood cell that has a lineage independent of the granulocyte, B-cell, and T-cell lineages.

NK cells are capable of killing virus-infected and malignant cells.

neutrophil A mature white blood cell in the granulocyte lineage formed in bone marrow. It has a nucleus with three to fi ve lobes and is phagocytic.

nonspecifi c immune response General defense mechanisms that are inherited as part of the innate structure and function of

Dental plaque and Dental Caries

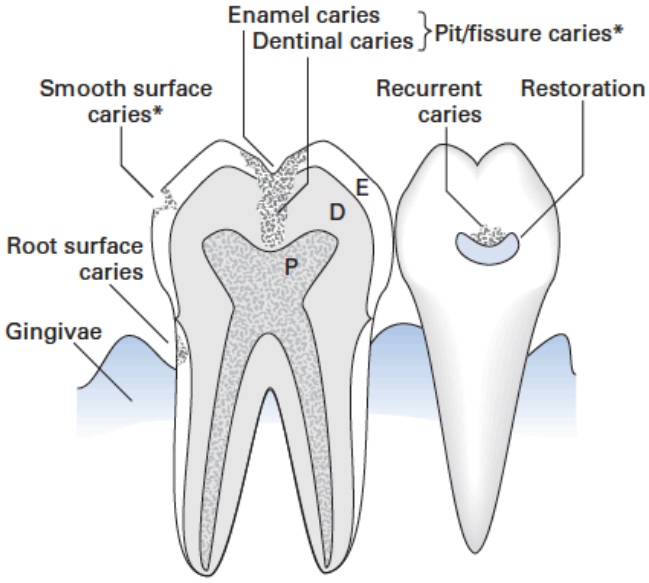
Dental plaque is a biofilm or mass of bacteria that grows on surfaces within the mouth. It is a sticky colorless deposit at first, but when it forms tartar, it is often brown or pale yellow. It is commonly found between the teeth, on the front of teeth, behind teeth, on chewing surfaces, along the gumline, or below the gumline cervical margins.

Dental caries is a chronic endogenous infection caused by the normal oral commensal flora. The carious lesion is the result of demineralization of enamel (and later of the dentine) by acids produced by plaque microorganisms metabolize dietary carbohydrates and the cavitation occur . once the surface layer of enamel has been lost the infection progresses to dentine, becoming firstly inflamed and then necrotic.

Classification of dental caries

Dental caries can be classified with respect to the site of the lesion

- pit or fissure caries (seen in molars, premolars and the lingual surface of maxillary incisors)
- smooth surface caries (seen mainly on approximal tooth surface just below the contact point)
- root surface caries (seen on cementum or dentine when the root is exposed to the oral environment)
- recurrent caries (associated with an existing restoration)



Nomenclature of dental caries. D, dentine; E, enamel; P, pulp.
*Also termed occlusal caries.

Aetiology

The major factors involved in the caries

- Host factor (tooth and saliva)
- Diet
- Microorganisms

Host factor

Tooth structure

Some areas of the same tooth are much more susceptible to carious attack than others, possibly because of difference in mineral content (especially fluoride).

Flow rate and composition of saliva

-The mechanical washing action of saliva is a very effective mechanism in the removal of food debris and unattached oral microorganisms.

- it has buffering capacity

-it acts as a delivery vehicle for fluoride.

Diet

There is a direct relationship between dental caries and the intake of carbohydrates. The most cariogenic sugar is sucrose. Sucrose is highly soluble and diffuse easily into the dental plaque acting as a substrate for production of extracellular polysaccharides and acids. For example, Cariogenic streptococci produce water-unsoluble **glucan** from sucrose, which **in addition** to facilitating **initial adhesion** of the organism to the tooth surface, it serves as a **nutritional source and matrix** for farther plaque development.

Other cariogenic carbohydrates are glucose and fructose.

Microbiology

Microorganisms in the form of dental plaque is a prerequisite for the development od dental caries.

Dental plaque hypothesis

There two hypotheses for dental plaque and caries according to the relationship with microorganisms:

1- The specific plaque hypothesis: One or more specific group of bacteria are principally involved in caries (e.g. *mutans* streptococci group).
2- Non-specific plaque hypothesis: the disease is caused by heterogenous mixture of non-specific bacteria.

The role of *mutans* streptococci

The species *Streptococcus mutans,* with its serotypes (c, e, f and s), and *Streptococcus sobrinus,* with serotypes d and g, are the most commonly found in humans.

The evidences of their role in dental caries are:

- Correlation between mutans streptococci counts in saliva and plaque with prevalence and incidence of caries.

- production of extracellular polysaccharides from sucrose and intracellular polysaccharides as glycogen (acts as a food store for use within dietary carbohydrate are low. .
- Ability to produce and maintain microbial growth to continue acid production.
- Rapid metabolism of sugars to lactic and other organic acids.
- Ability to attain the critical PH for enamel demineralization more rapidly than other common plaque bacteria.

The role of lactobacilli

lactobacilli has impotent role in dental caries. because of:

- Their high numbers in most carious lesions affectiig enamel.
- The positive correlation between their number in plaque and saliva and caries activity.
- Their ability to grow in low-pH environments and to produce lactic acid.
- Their ability to produce extracellular and intracellular polysaccharides.

It is so important to mention that lactobacilli are rarely isolated from plaques before the development of caries. It is believed that they are involved more in the progression of the deep enamel lesion.

The role of *Actinomyces spp.*

Actinomyces spp. are associated with development of root surface caries.

The role Veillonella

Veillonella is gram -negative anaerobic coccus that is present in significant numbers in most supragingival plaque samples.

Plaque metabolism and dental caries

Oral bacteria have developed a number of regulatory mechanisms, which act at three pathways:

1. transport of sugar into the organisms
2. the glycolytic pathway.
3. conversion of pyruvate into metabolic end products.

The bacterial metabolism products are responsible for enamel demineralization. The process begins when dietary sugar is broken down by bacterial extracellular enzymes such as glucosyl and fructosyl transferases, with the release of glucose and fructose, respectively. These monosaccharides are then converted into polysaccharides glucans and fructans, respectively. Glucans are mostly used as a major bacterial food source; the fructans contribute to the plaque matrix while facilitating the adhesion and aggregation of plaque bacteria and serving as a ready, extracellular food source.

During glycolysis, glucose is degraded immediately by bacteria via the glycolytic pathway with production of two bacterial molecules from each molecule of glucose. The pyruvate can degraded farther into other chemical molecules.

- under low sugar condition, pyruvate is converted into ethanol, acetate and formate.
- in high sugar level, pyruvate is converted into lactate molecules.

Different species produce acids at different rate and very in their ability to survive under such conditions. the mutens streptococci bacteria reduce the plaque PH to low levels creating hostile conditions for other plaque bacteria.

Microbiology of root surface caries

Approximately 60% of individuals in the West aged 60 yeas or older now have root caries. This has arisen mainly because of the reduction in enamel caries and

the consequential retention of teeth later into life, accompanied by gingival recession. The soft cemental surface thus exposed are highly susceptible to microbial colonization, due to their irregular and rough surfaces.

Prevention of dental caries

The major approaches to prevention of caries are:

1- Sugar substitutes: stopping or reducing between-meal consumption of carbohydrates or substituting non-cariogenic artificial sweeteners.
2- Fluorides: making the tooth structure less soluble to acid attack by using fluorides rich products.
3- Sealants: to protect susceptible areas of the tooth (e.g. pit and fissures) that cannot easily be kept plaque-free by routine oral hygiene measures.
4- Reducing cariogenic flora.
5- Probiotics replacement of cariogenic bacteria by organisms with low or no cariogenic potential.

Bacterial physiology

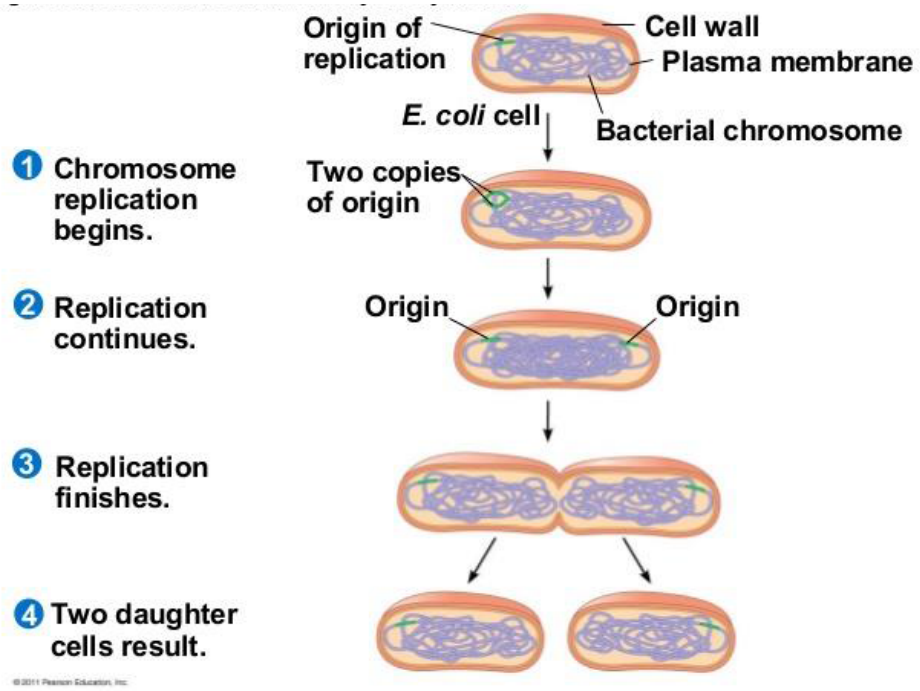
Microbial Growth

When microbes are provided with nutrients and the required environmental factors, they become metabolically active and grow. Growth takes place on two levels.

- Cell synthesizes new cell components and increases its size.
-The number of cells in the population increases.

The size of population is increased due to the bacterial cell multiplication by cell division. This has tremendous importance in microbial control, infectious disease, and biotechnology.

The division of a bacterial cell occurs mainly through binary, or transverse, fission. During binary fission, the parent cell enlarges, duplicates its chromosome, and forms a central transverse septum that divides the cell into two daughter cells. This process is repeated at intervals by each new daughter cell in turn; and with each successive round of division, the population increases.



Bacterial Nutritional requirements

Bacterial requirements for growth include oxygen, hydrogen and carbon), inorganic ions and organic nutrients.

Hydrogen is usually obtained from water, and **oxygen** is obtained from atmosphere or from water where it is found in dissolved state.

Carbon: according to their ability to synthesize essential metabolism (obtained carbon), bacteria can be classified into the following types:

A- Autotrophs:- These bacteria are able to synthesize their own organic food from inorganic substances. They use carbon dioxide for obtaining carbon

B- Heterotrophs:-Microbes obtain their carbon from organic compound, such as sugar, protein and lipids.

Inorganic ions; Nitrogen, sulphur, phosphate, potassium and some other elements.

Organic nutrients:- Organic nutrients are required in small amounts by cells because they play specific roles in biosynthesis. Growth factors are organized into three categories.

1- purines and pyrimidines: required for synthesis of nucleic acids (DNA and RNA)
2- amino acids: required for the synthesis of proteins
3- vitamins: needed as coenzymes and functional groups of certain enzymes

Factors that modify bacterial growth

pH:-

according to their acidity requirements bacteria can be classified into:

1-Acidophiles:- Microorganisms which grow at pH (3-5).
2- Neutrophiles:- Microorganisms which grow best at neutral pH (6-8)
3- Alkaliphiles:- Microorganisms which grow best under alkaline conditions pH as high as 10.5.

Gas requirement:-

Microorganisms fall into several groups with respect to the effect of oxygen on their growth and metabolism:

1. Obligate aerobes
- Oxygen is essential for growth of these bacteria.
- examples: *Pseudomonas aeruginosa*

2. Obligate anaerobes
- These bacteria are not need or use O2 as a nutrient. Or in other words: only grow in absence of Oxygen
- examples: Clostridium, Bacteroides

3. Facultative anaerobes
- These bacteria grow in presence or absence of Oxygen. Under anaerobic conditions (no O2) they grow by fermentation, or anaerobic respiration, but in the presence of O2 they switch to aerobic respiration.
-it may be sub grouped as capnophiles or capnophilic organisms if they grow well in the presence of 8-10% carbon dioxide.
- examples: all Enterobacteriaceae (*E.coli*), some Bacillus

4. Aerotolerant anaerobes
- Grow either with or without oxygen, but metabolism remains fermentative and do not use oxygen
- examples: *Enterococcus faecalis*, some Lactobacillus

5-Microaerophilec
-these bacteria grow well under low oxygen concentration
-examples: *Campylobacter fetus*

Temperature:-

The temperature range at which organism grow best is called optimum temperature. In human parasitic organism optimum temperature ranges between 30° C and 37° C. there are three groups of bacteria as regard to the temperature:-

1- Psychrophilic:- The bacteria is growing between 0° C and 25° C. they are mostly soil and water bacteria

2- Mesophilic:- Some bacteria grow between 20° C and 44° C this group include bacteria producing disease.

3- Thermophilic:- The bacteria can grow between 50 and 80° C this bacteria will survive after pasteurization processes of milk.

The Rate of Population Growth

The time required for a complete fission cycle—from parent cell to two new daughter cells—is called the **generation**, or **doubling time**. In bacteria, each new fission cycle or generation increases the population by a factor of 2, or doubles it.

The length of the generation time is a measure of the growth rate of an organism. The average bacterial generation time is 30 to 60 minutes under optimum conditions.

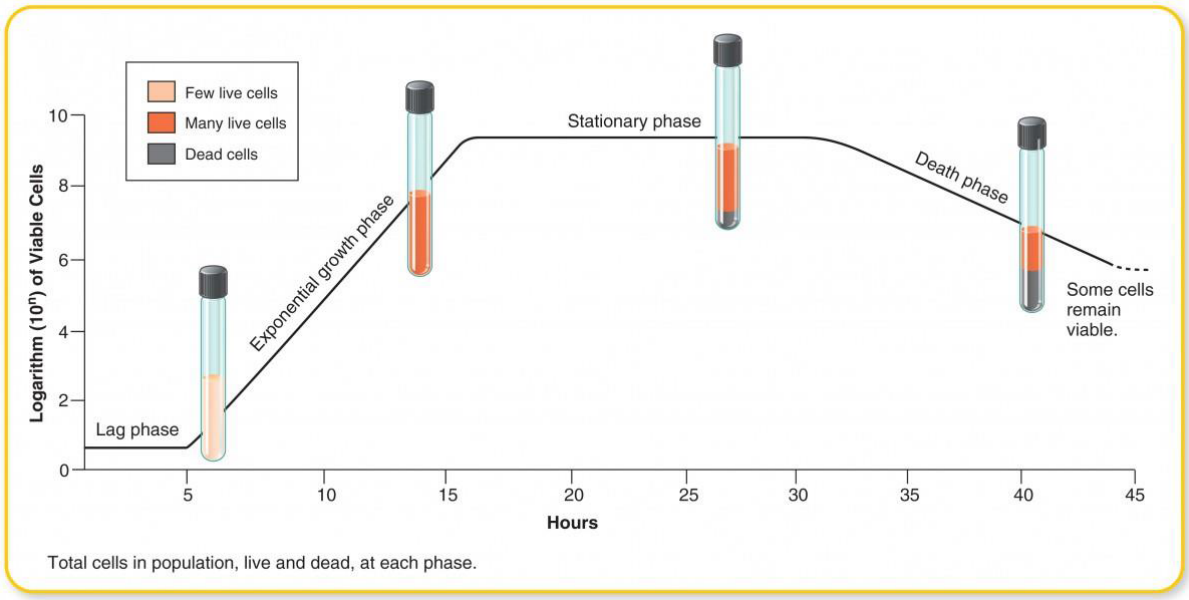
The shortest generation times average 5 to 10 minutes, and longer generation times require days.

Some bacterial species, for example, *Mycobacterium leprae* (the cause of Hansen's disease), has a generation time of 10 to 30 days.

Most pathogenic bacteria have relatively short doubling times. *Salmonella enteritidis* and *Staphylococcus aureus*, bacteria that cause food-borne illness, double in 20 to 30 minutes.

Stages in the Normal Growth Curve

Data from an entire growth period of 3 to 4 days typically produce a curve with a series of phases termed the lag phase, the exponential growth (log) phase, the stationary phase, and the death phase .



Total cells in population, live and dead, at each phase.

I-The lag phase is an early "flat" period on the graph when the population appears not to be growing or is growing at less than the exponential rate. Growth lags primarily because

1. The newly inoculated cells require a period of adjustment, enlargement, and synthesis of DNA, enzymes, and ribosomes.

2. The cells are not yet multiplying at their maximum rate.

The length of the lag period varies from one population to another, depending on the condition of the microbes and medium.

II-Logarithmic or log phase :The cells reach the maximum rate of cell division during the **exponential growth** (logarithmic or log) phase, a period during which the curve increases in a straight line. This phase will continue as long as cells have adequate nutrients and the environment is favourable. During this phase, the population achieves its potential generation time, and bacterial growth is genetically coordinated.

III-stationary growth phase: The population enters a survival mode in which cells stop growing or grow slowly. The curve levels are off, as the rate of cell inhibition or death is equal or so close to the rate of cell multiplication. The

number of viable cells has reached maximum and remains relatively constant during this period.

The death phase : The decline in the growth rate is caused by several factors.

1-Depletion of nutrients and oxygen.
2-Increased cell density often causes an accumulation of organic acids and other toxic biochemical.

Cells begin to die at an exponential rate and most are unable to multiply. The curve now dips downward as the death phase begins. The speed with which death occurs depends on the relative resistance of the species and how toxic the conditions are, but it is usually slower than the exponential growth phase.

Bacterial genetics

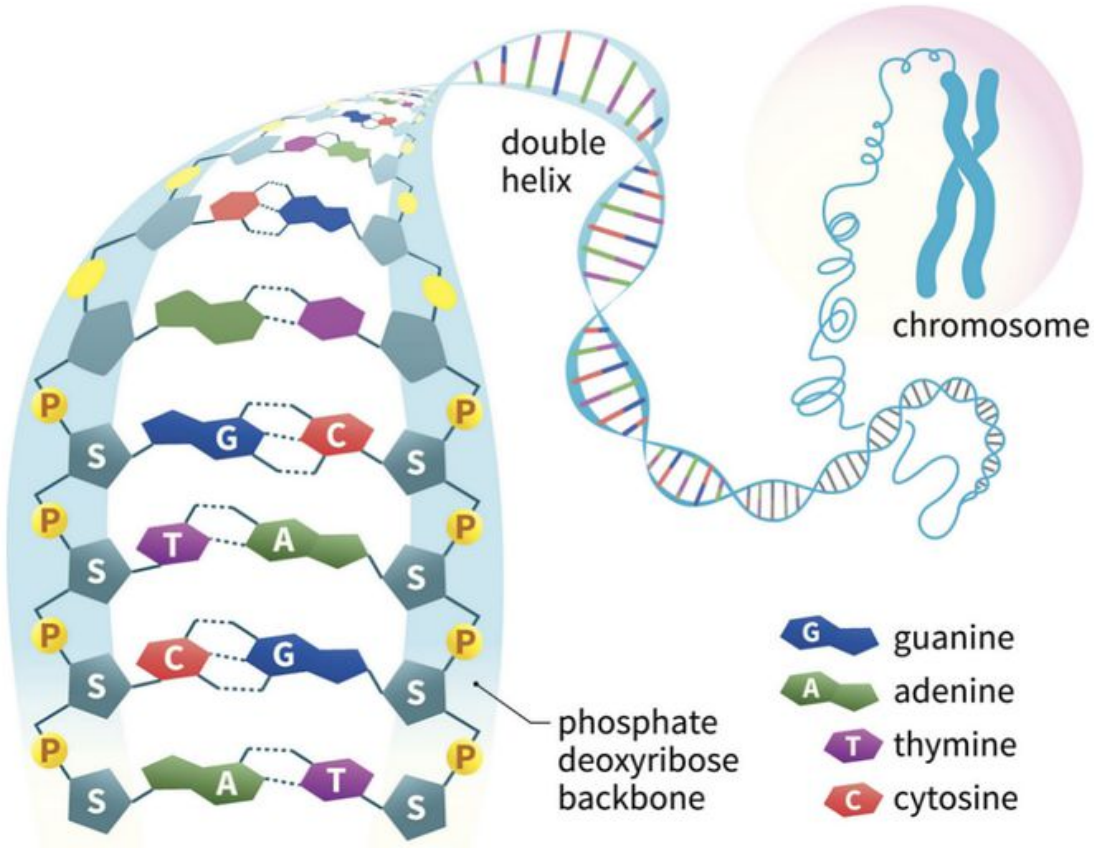
Genetics is the study of the inheritance and variation. All bacterial characteristics are encoded in DNA. DNA or **Deoxyribonucleic acid** is a molecule composed of two chains (made of nucleotides) that coil around each other to form a double helix carrying all the genetic instructions that used in the growth, development, functioning and reproduction of all known living organisms and many viruses. DNA and ribonucleic acid (RNA) are nucleic acids; alongside proteins, lipids and complex carbohydrates (polysaccharides), which all are the four major types of macromolecules that are essential for all known forms of life.
The two DNA strands are also known as polynucleotides since they are composed of simpler monomeric units called nucleotides.

Each DNA nucleotide is composed of one of four nitrogen-containing nucleobases (cytosine[C], guanine [G], adenine [A] or thymine [T]), a sugar called deoxyribose, and a phosphate group. The nucleotides are joined to

one another in a chain by covalent bonds between the sugar of one nucleotide and the phosphate of the next, resulting in an alternating sugar-phosphate backbone. The nitrogenous bases of the two separate polynucleotide strands are bound together, according to base pairing rules (A with T and C with G), with hydrogen bonds to make double-stranded DNA.

The complementary nitrogenous bases are divided into two groups, pyrimidines [C,T, and uracil U (exist in the RNA strand instead of T)].

and purines (G and A). In DNA, the pyrimidines are thymine and cytosine; the purines are adenine and guanine.



The DNA of most bacteria is contained in a single circular molecule, called the bacterial chromosome. The chromosome, along with several proteins and RNA molecules, forms an irregularly shaped structure called the nucleoid. This sits in the cytoplasm of the bacterial cell.

Genes

The genetic code of bacteria is contained in a series of units called genes. As the normal bacterial chromosome has one copy of each gene, bacteria are called **haploid** organisms (higher organisms which contain two copies of the gene called diploid).

A gene is a chain of purine and pyrimidine nucleotides. the genetic information is encoded in triple nucleotide groups or codons. Each codon codes for specific amino acid or regulatory sequence, e.g. starts and stope codons. In this way the structural genes determine the sequence of amino acids that form the protein, which is the gene product.

Genetic variation in bacteria

Genetic variation can occur as a result of mutation or gene transfer.

A- Mutation

Mutation is a change in the base sequence of DNA, as a consequence of which different amino acids are incorporated into a protein, resulting in an altered phenotypes. There are three types of DNA mutations.

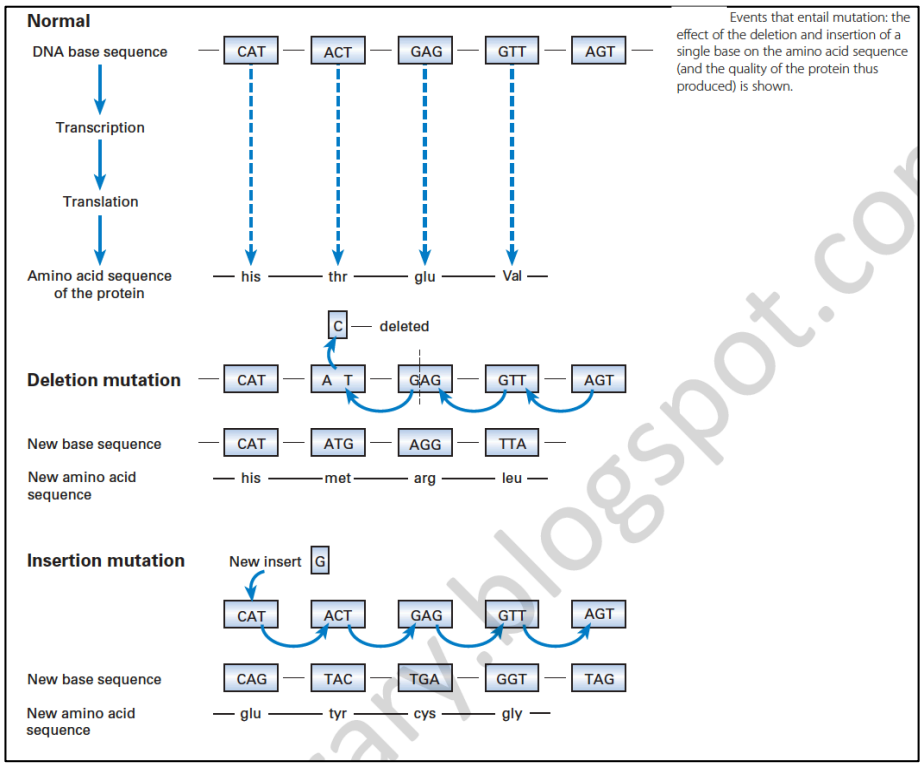
1 Base substitution : this occurs during DNA replication when one base is inserted in place of another. And it has two types

   -Missense mutation: when the base substitution results in a codon that instructs a different amino acid to be inserted.

   -nonsense mutation: when the gene mutation stops its protein synthesis.

2 Frame shift mutation: which occur when one or more base pair are added or deleted that resulted in production of inactive protein because of the production of wrong amino acids.

3 Insertion : the insertion of additional pieces of DNA.



B-Gene transfer

the transfer of genetic information can occur by:

1. Conjugation
2. Transduction
3. Transformation
4. Transposition

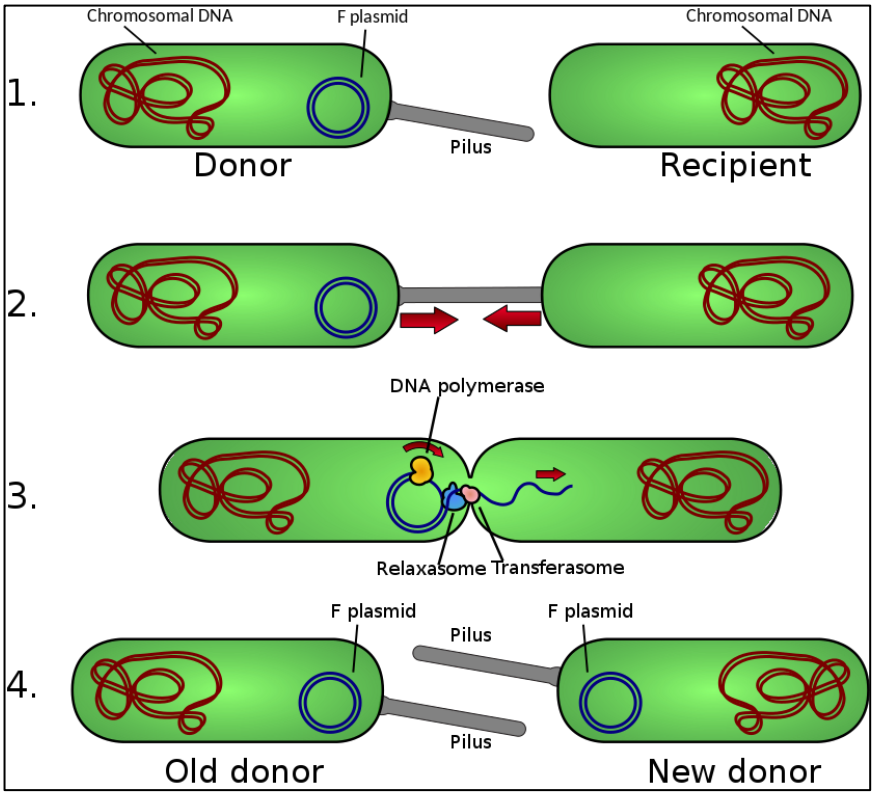
Conjugation

Bacterial conjugation is the transfer of genetic material between bacterial cells by direct cell-to-cell contact (mating of two cells) or by a bridge-like connection between two cells. This takes place through pilus (Pili in plural).

It is one of horizontal gene transfer mechanisms. During conjugation the *donor* cell provides a conjugative or mobilizable genetic element that is most often a plasmid or transposon. Most conjugative plasmids have systems ensuring that the *recipient* cell does not already contain a similar element.

The genetic information transferred is often beneficial to the recipient. Benefits may include antibiotic resistance, xenobiotic tolerance or the ability to use new metabolites. The mating process is controlled by an F (fertility) plasmid ,carrying genes for the proteins required for mating including pilin, which forms pilus.

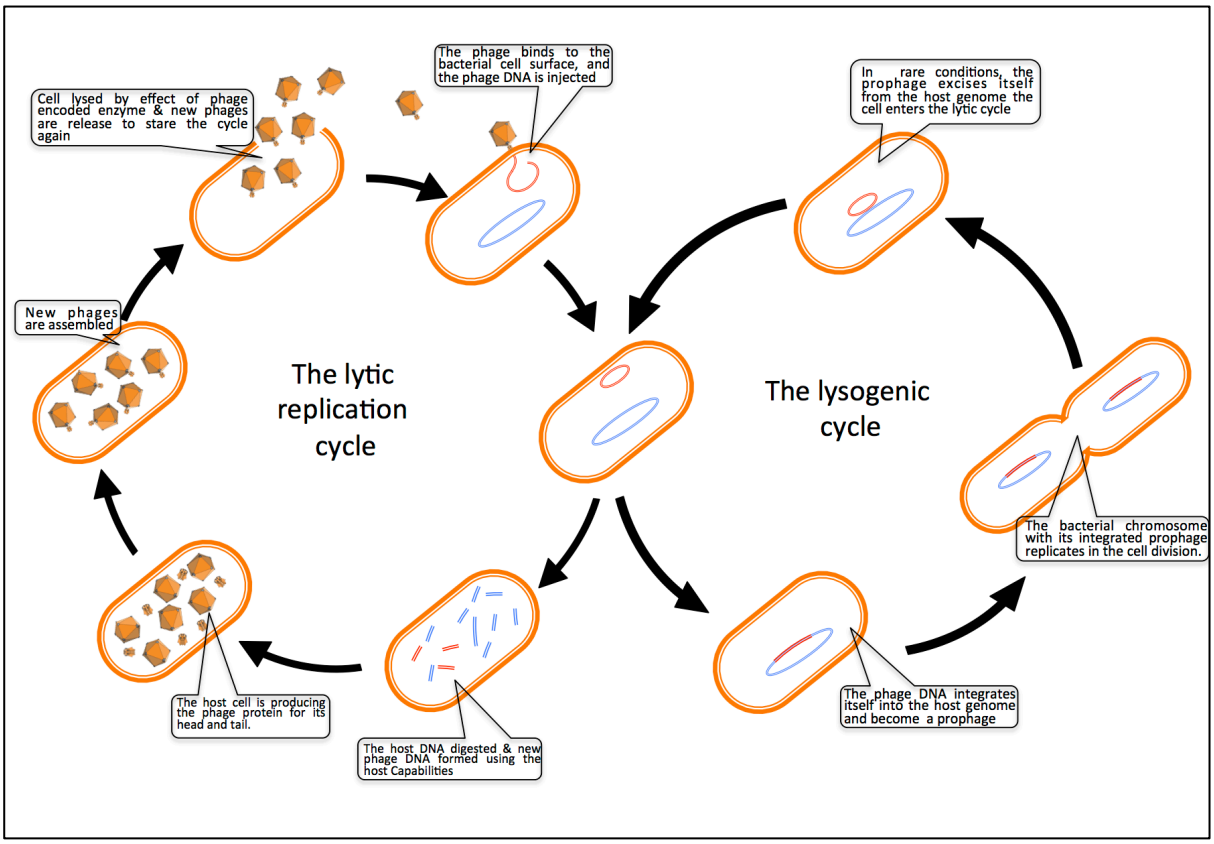
1. Donor cell [cell carrying F factor or (F+)] produces pilus.
2. Pilus attaches to recipient cell and brings the two cells together.
3. The mobile plasmid is cleaved enzymatically and a single strand of DNA is then transferred to the recipient cell.
4. Both cells synthesize a complementary strand to produce a double stranded circular plasmid and are able to reproduce pili; both cells are now viable donor for the F-factor.



Schematic drawing of bacterial conjugation.

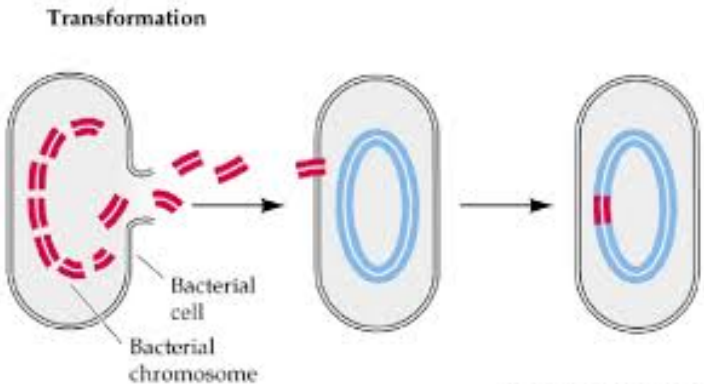
Transduction

Transduction is a process of DNA transfer by means of bacterial virus (bacteriophage or phage). The are two life cycle of the bacteriophage, lysogenic (the phage inject its genome inside bacterial genome and stays stable) and replication life (they replicate inside the bacterial cell using all its metabolic mechanisms) cycles. When the lysogenic bacteria be inducted (by UV light or antibiotic) and starts the replication action of the phage, within the host bacterial cell, a piece of bacterial DNA is incorporated accidentally in to the phage particle and is carried to the recipient cell at the time of next infection.



Transformation

This is the transfer of exogenous of bacterial DNA from one cell to another. It occurs in nature when dying bacteria release their DNA, which is than taken up by recipient cells and recombined with the recipient cell's DNA.



Transposition

This occurs when transposable element moves from one DNA site to another within the same genome of the same organism.

The simplest transposable elements, called; insertion sequences, are less than 2 kilobases in length and encodes enzymes (transposase) required for "DNA jumping" from one site to another.

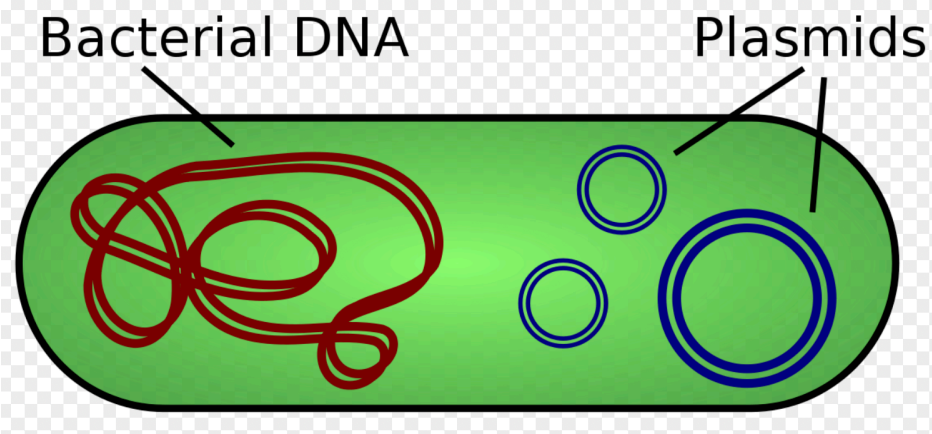
DNA recombination

The transferred DNA from the donor cell to the recipient cell is integrated into the host genome by a process called DNA recombination. There are two types of DNA recombination depends on DNA homology between the two recombinant molecules:

1- Homologous recombination
2- Nonhomologous recombination.

Plasmids

A **plasmid** is a small DNA molecule within a cell that is physically separated from a chromosomal DNA and can replicate independently. They are most commonly found as small circular, double-stranded DNA molecules in bacteria; however, plasmids are sometimes present in archaea and eukaryotic organisms. In nature, plasmids often carry genes that may benefit the survival of the organism, for example antibiotic resistance. While the chromosomes are big and contain all the essential genetic information for living under normal conditions, plasmids usually are very small and contain only additional genes that may be useful to the organism under certain situations or particular conditions. Artificial plasmids are widely used as vectors in molecular cloning, serving to drive the replication of recombinant DNA sequences within host organisms. In the laboratory, plasmids may be introduced into a cell via transformation.



Bacillus and *Clostridium*

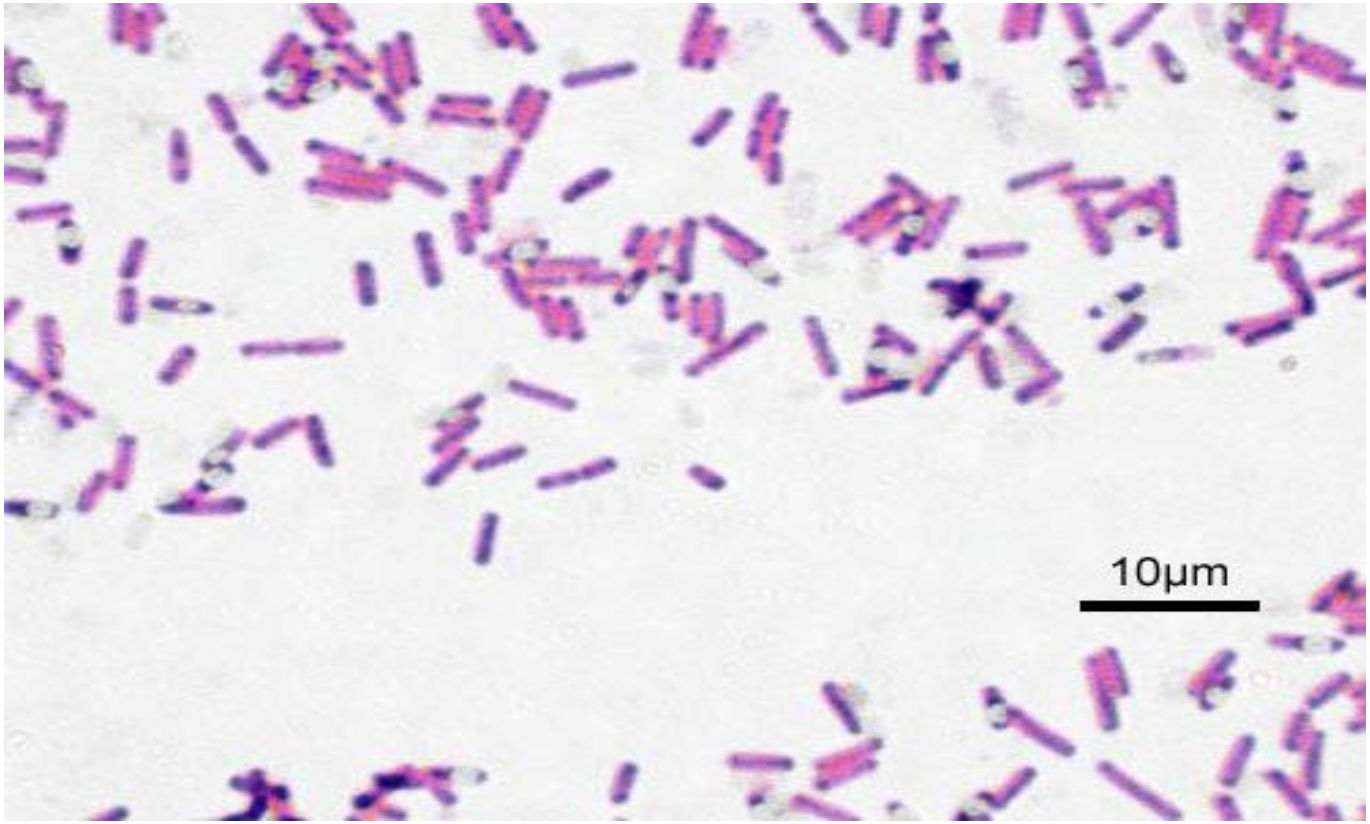
Medical microbiology
Third year

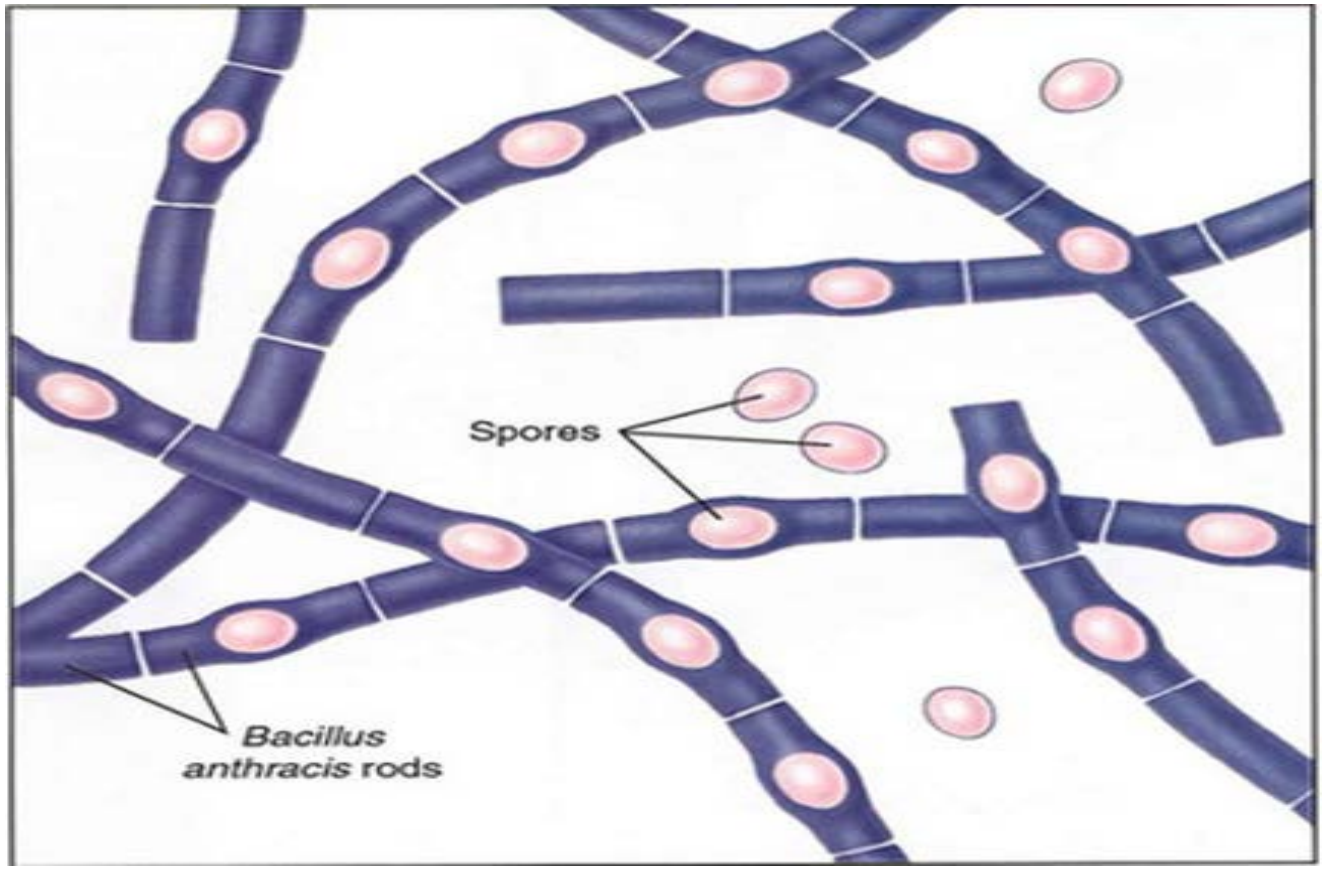
Bacillus

- **Bacillus**, (genus *Bacillus*), any of a genus of rod-shaped, gram-positive, endospore-forming, aerobic or (under some conditions) anaerobic bacteria widely found in soil and water. Some types of *Bacillus* bacteria are harmful to humans, plants, or other organisms. For example, *B. subtilis* is a common contaminant of laboratory cultures and is often found on human skin. Most strains of *Bacillus* are not pathogenic for humans but may, as soil organisms, infect humans incidentally. A notable exception is *B. anthracis*, which causes anthrax in humans and domestic animals.

Gram positive Bacillus



This figure clearly shows the spores on the rod shaped B. anthracis



Bacillus anthracis

Anthrax is caused by *Bacillus anthracis,* • humans acquire the disease directly from contact with infected herbivores or indirectly via their products. The clinical forms include:

(1) Cutaneous anthrax (eschar with • edema),generally occurs on exposed surfaces of the arms, face and neck through wound contamination by the spores of organism.

(2) Intestinal anthrax, from eating infected meat.

-

(3) Pulmonary anthrax(wool sorter’s disease), from inhaling spore-laden dust.

-

Virulence factors

The virulence factors of *B anthracis* are its capsule and anthrax toxin.

-

Diagnosis

- The typical morphology of the bacillus: in clinical material *B. anthracis* are Gram-positive thick, long, straight bacilli with square or truncated ends with parallel sides found usually single, in pairs or chains of 3 or 4 bacilli. The chain of bacilli with truncated and swollen ends gives a characteristic “bamboo stick” appearance.

Central
Subterminal

Gram stain of Bacillus anthracis

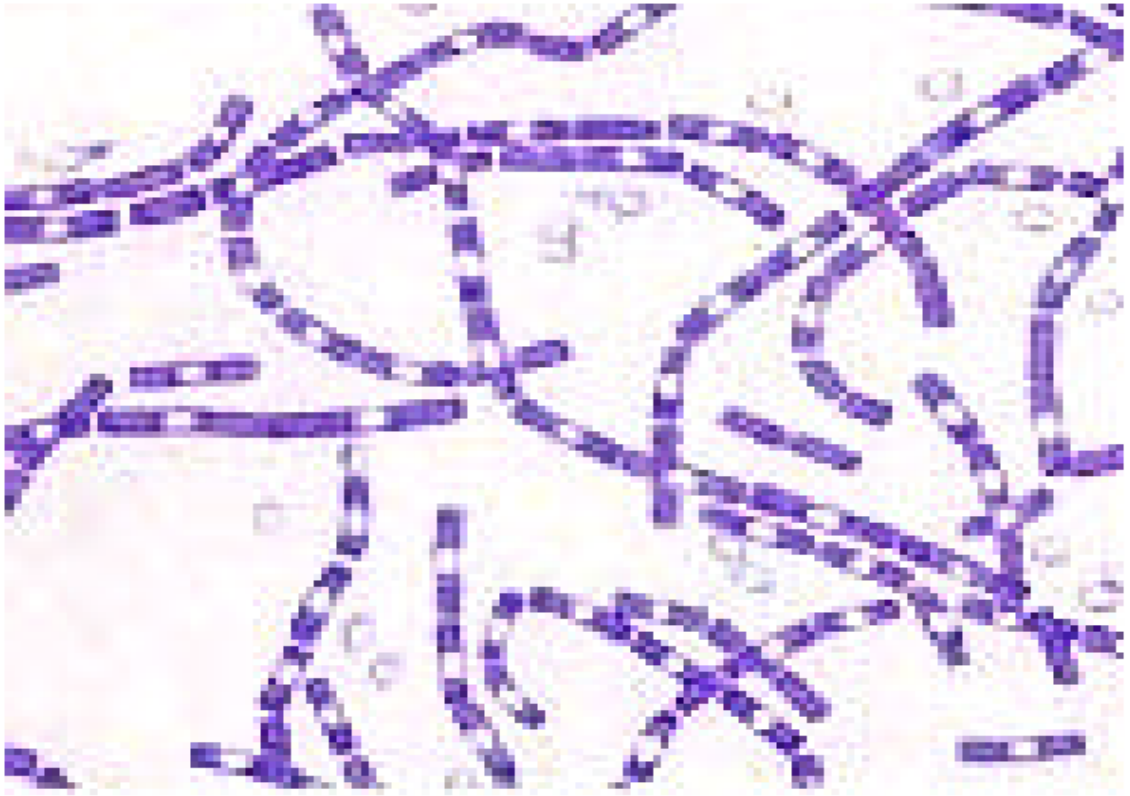

Figure 1 Gram-stained *Bacillus anthracis*. Characteristic boxcar

Culture media

Nutrient agar •

After overnight incubation at 35–37 °C • colonies are large, 2–3 mm in diameter, irregular, raised, dull, opaque and greyish-white with “frosted glass” (ground glass) This is the so-called “Medusa head appearance”.

Bacillus species on Chocolate agar

Blood agar •

After overnight incubation at 35–37 °C on • horse or sheep blood agar (BA), colonies of freshly isolated *B. anthracis* are white, or grey-white and non-haemolytic.

Blood agar no haemolysis

Spores •

- For diagnostic purposes, they can generally be visualized in smears of standard laboratory agar plate cultures (e.g. blood agar or nutrient agar) after 20–24 hours of incubation at 35 °C to 37 °C. The spores are central/subterminal.

- In Gram-stained preparations, the developing spores appear as unstained areas within the cell. With malachite green/safranin (or malachite green/basic fuchsin) staining, the spores are stained green and the vegetative forms are pink.

In the Ziehl-Neelsen staining, spores are pink and the vegetative forms are blue.

-

Capsules •

They can be induced either by growth in • bicarbonate agar containing serum under a 5%–20% carbon dioxide atmosphere, or in defibrinated blood or in serum (defibrinated horse blood seems to work best).

Selective agars – PLET

- Selective media are needed for the isolation of *B. anthracis* from clinical materials or environmental samples heavily contaminated with other bacteria. The best selective system was the polymyxin, lysozyme, EDTA and thallous acetate (PLET) agar.

Bicarbonate agar

- Colonies of bacillus anthracis of fully virulent isolates are mucoid in nature on this medium when incubated at an increased CO_2 tension (5%CO_2) due to capsule formation.
- This culture was probably enhances production of the the capsule and accounts for the mucoid colony type.

Bacillus anthracis

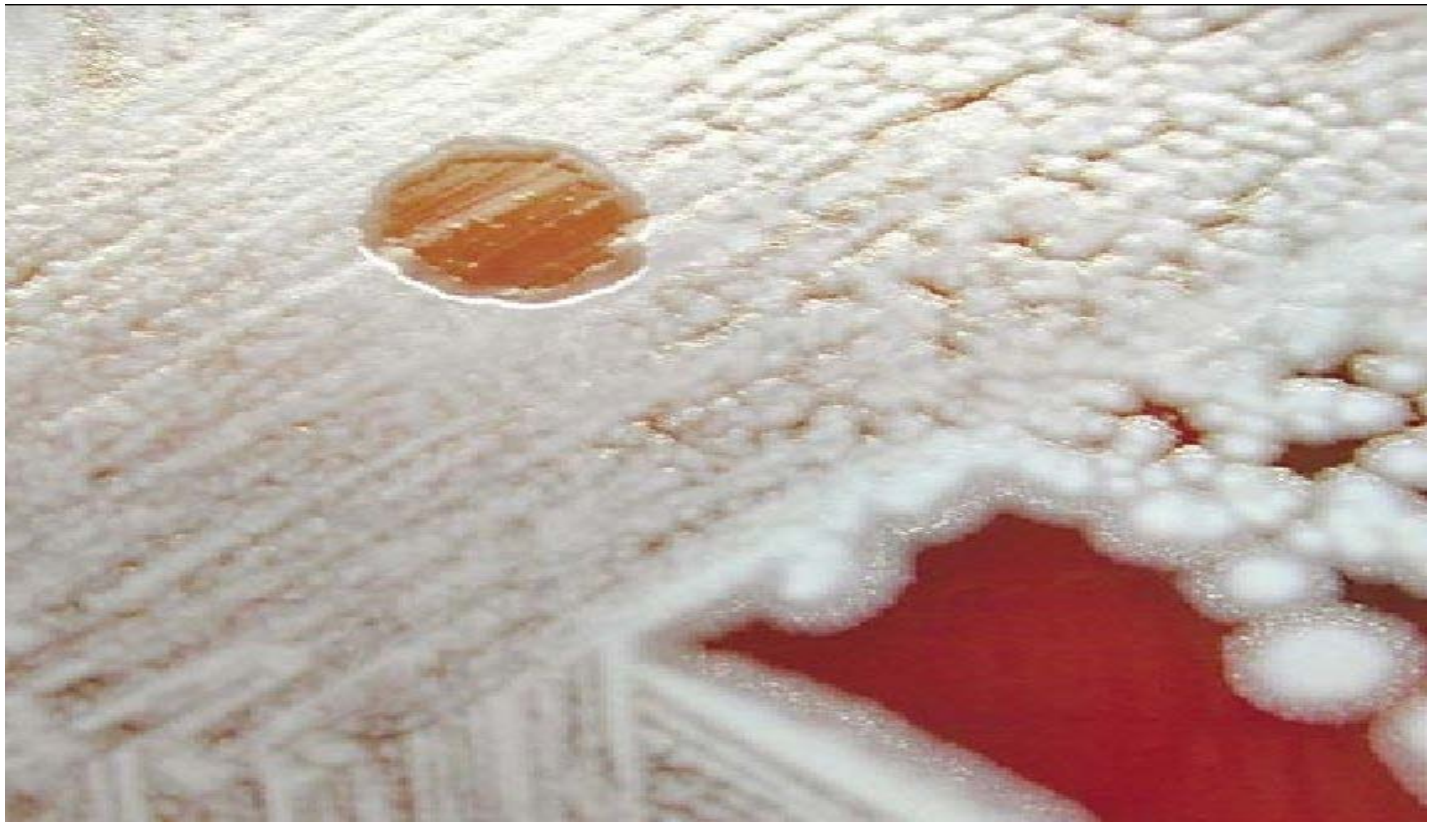
Susceptibility to penicillin G

- *B. anthracis* is susceptible to pencillin ,the zone of susceptibility will be visible after overnight incubation at 35–37 °C and incubation on medium containing low level of pencillin causes the bacterium to swell and form achain of cells that resemble a string of pearls .Other bacillus species are resistant to pencillin and do not exhibit this String of pearls reaction.

String of pearls

Susceptibility to the diagnostic ("gamma") bacteriophage(phage lysis):

- The diagnostic ("gamma") phage has the ability to lyse *B. anthracis* grown aerobically on blood or other nutrient agar and will not lyses any other *Bacillus* species.

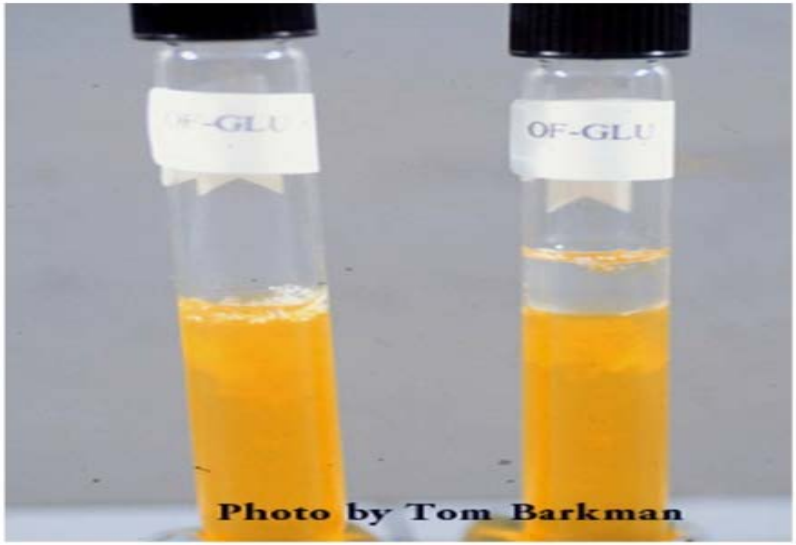


Biochemical reactions

- Glucose, maltose and sucrose fermented with acid but no gas
- Catalase positive

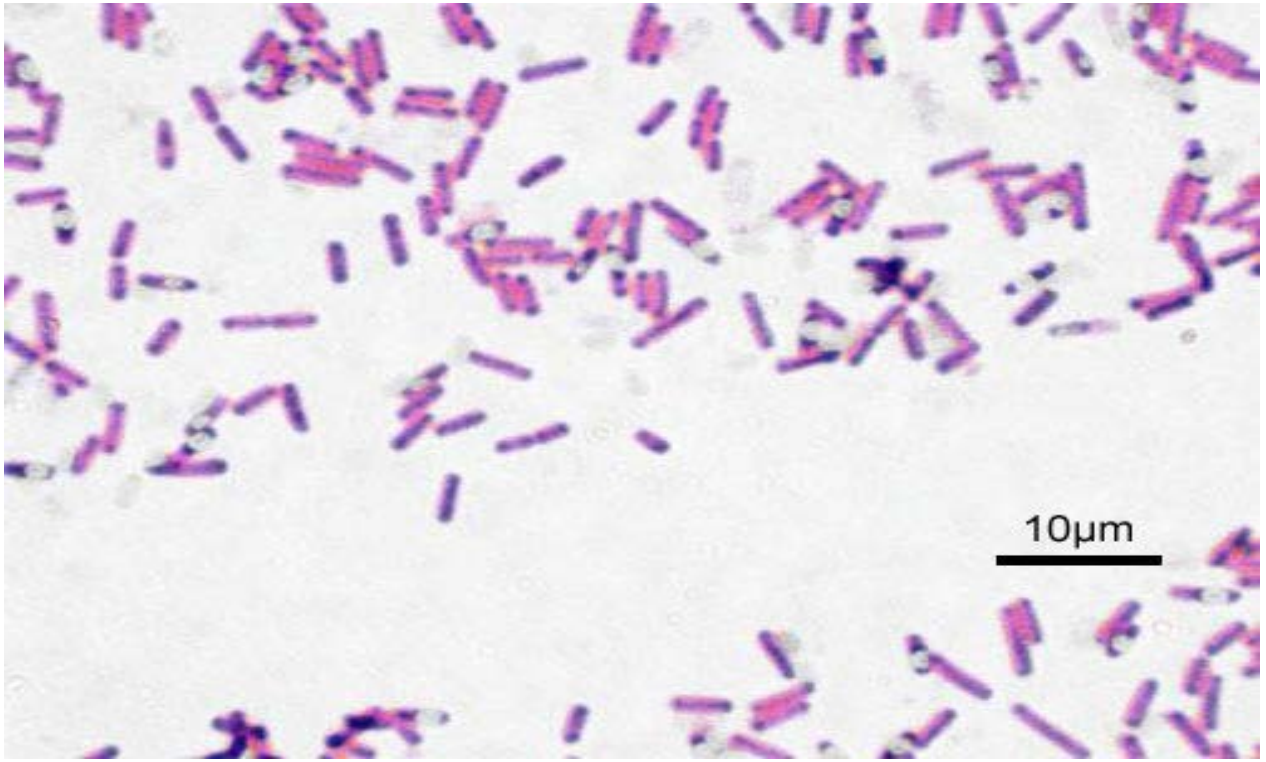
Biochemical Reactions

- Glucose, Maltose and Sucrose fermented with acid but no gas
- Catalase positive



Bacillus subtilis

- ***Bacillus subtilis***, is a Gram-positive, catalase-positive bacterium, found in soil and the gastrointestinal tract of ruminants and humans. *B. subtilis* is rod-shaped, and can form a tough, protective endospore, allowing it to tolerate extreme environmental conditions.

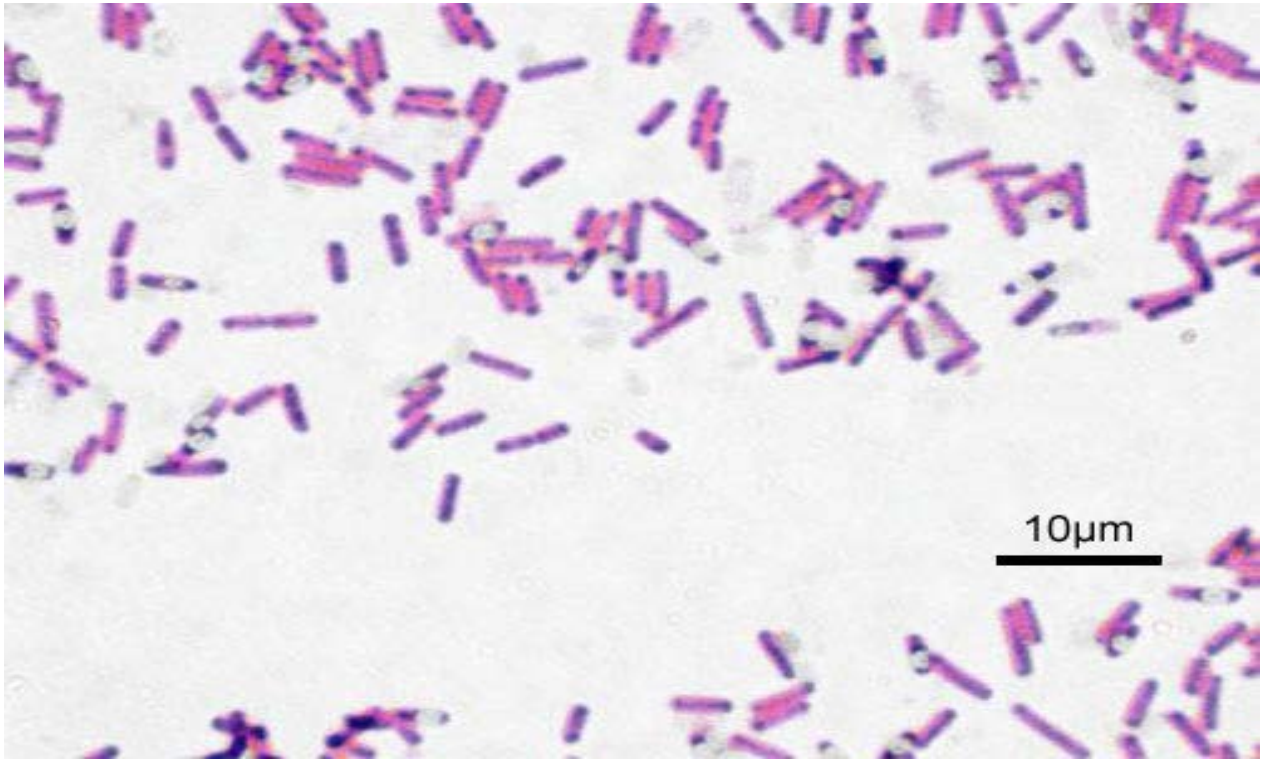


10μm

- Bacillus subtilis has on several occasions been isolated from human infections. Infections attributed to B. subtilis include bacteremia, endocarditis, pneumonia, and septicemia. However, these infections were found in patients in compromised immune states.

Diagnosis

- *Bacteria smearing, staining, and morphology*: The unknown bacteria were stained by Gram method and observed by optical microscope under the oil-immersion lens which show gram-positive, rod-shaped, and can form a tough, protective endospore.



10μm

- *Biochemical tests of the bacteria*: The unknown bacteria were subjected to carbohydrate fermentation test, indole formation negative, methyl red (MR)negative and VP tests positive, respectively.

Clostridium

Clostridium, genus of rod-shaped, usually gram-positive bacteria, members of which are found in soil, water, and the intestinal tracts of humans and other animals. Most species grow only in the complete absence of oxygen,highly resistant to heat, desiccation, and toxic chemicals and detergents. The species are variable in size.

-

Clostridium perfringens

- is an anaerobic gram-positive spore-forming bacillus that is associated with acute gastrointestinal infection ranging in severity from diarrhea to necrotizing enterocolitis and myonecrosis in humans. This pathogen possesses an arsenal of toxins that are responsible for disease pathogenesis and can form spores that are resistant to environmental stress.

1.Clostridium perfringens(Cl.welchii)

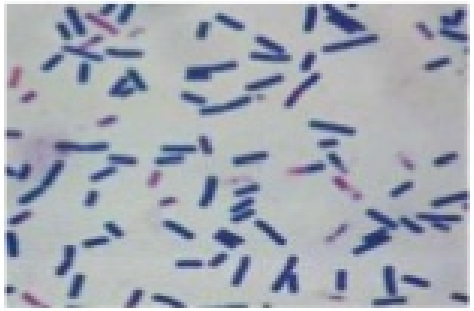
Morphology

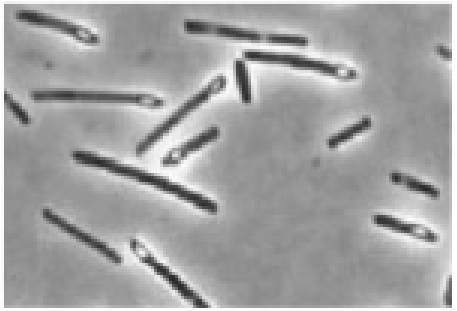
-Large Gram-positive bacilli with straight, parallel sides & slightly rounded ends.

-Measure 4-6x1µm in size,occuring singly or in chains

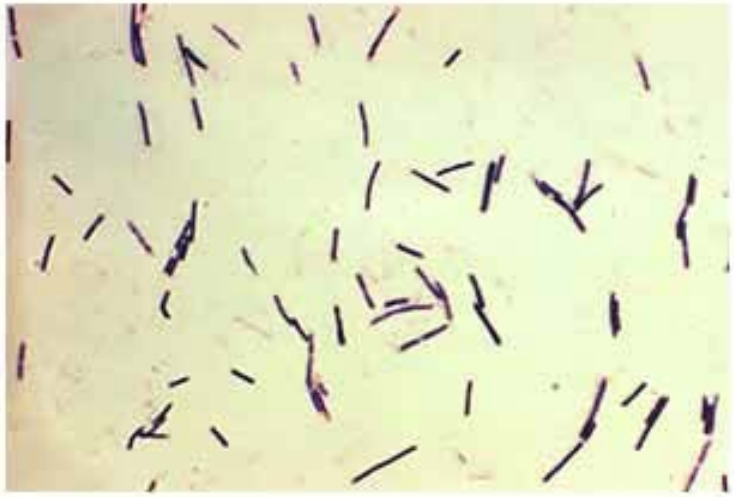
-Pleomorphic,capsulated & non-motile.

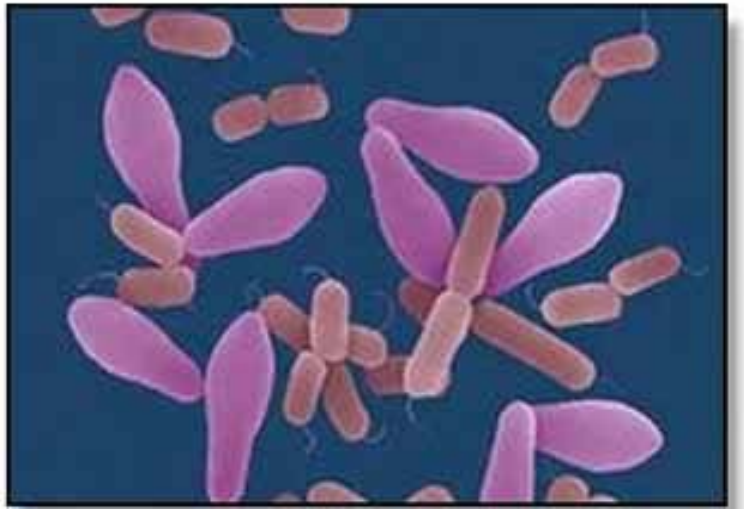
-Spores are **central or sub terminal**. **Spores are rarely seen in culture media or material from pathogenic lesions**, a characteristic morphologic feature

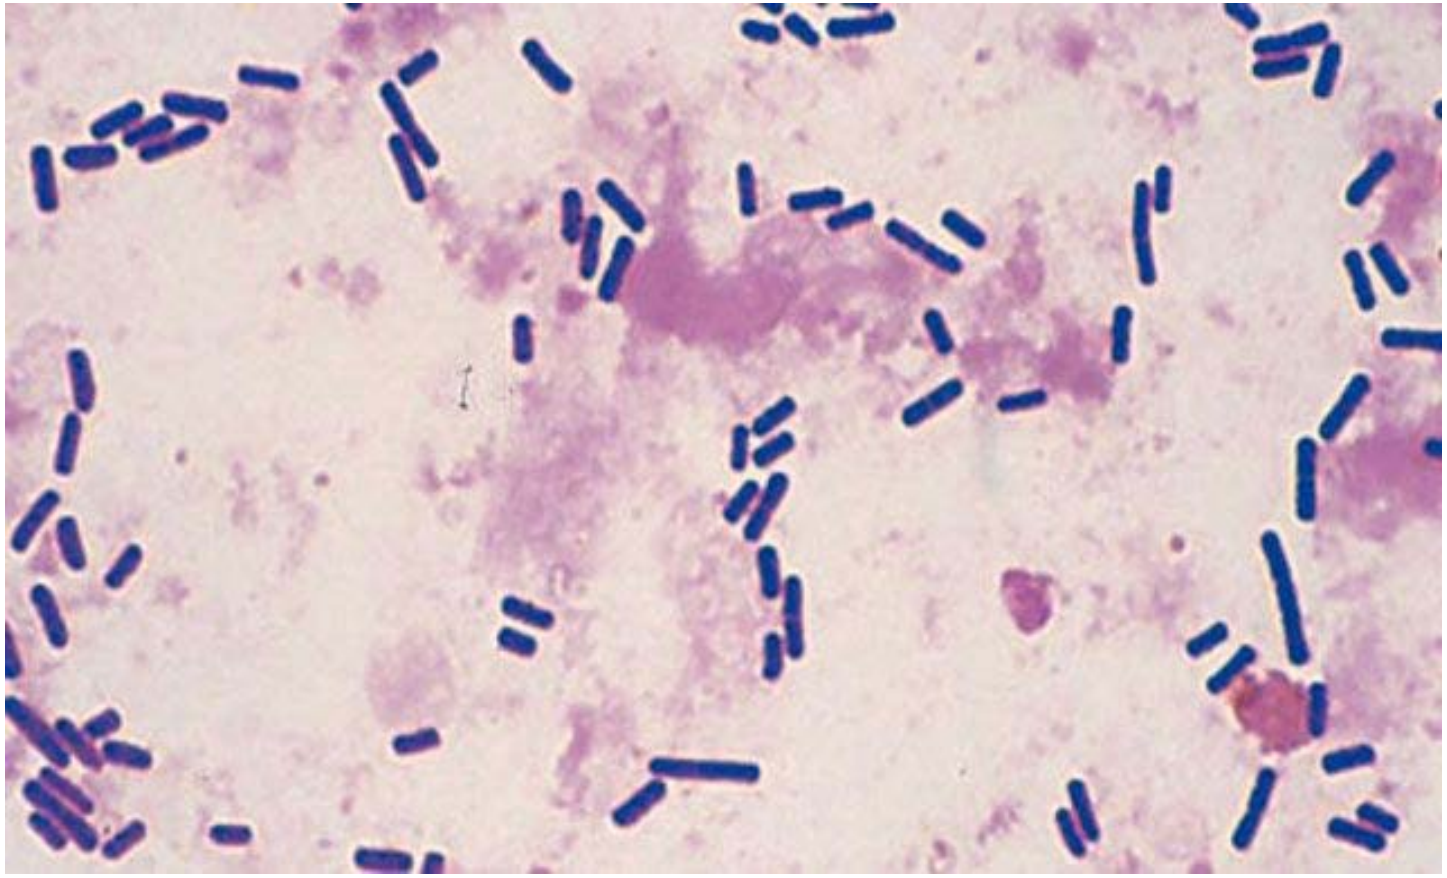




Morphology of *Clostridium perfringens*







PATHOGENICITY

-**Three Clinical conditions** produced include;

1.Simple wound contamination: Slow wound healing

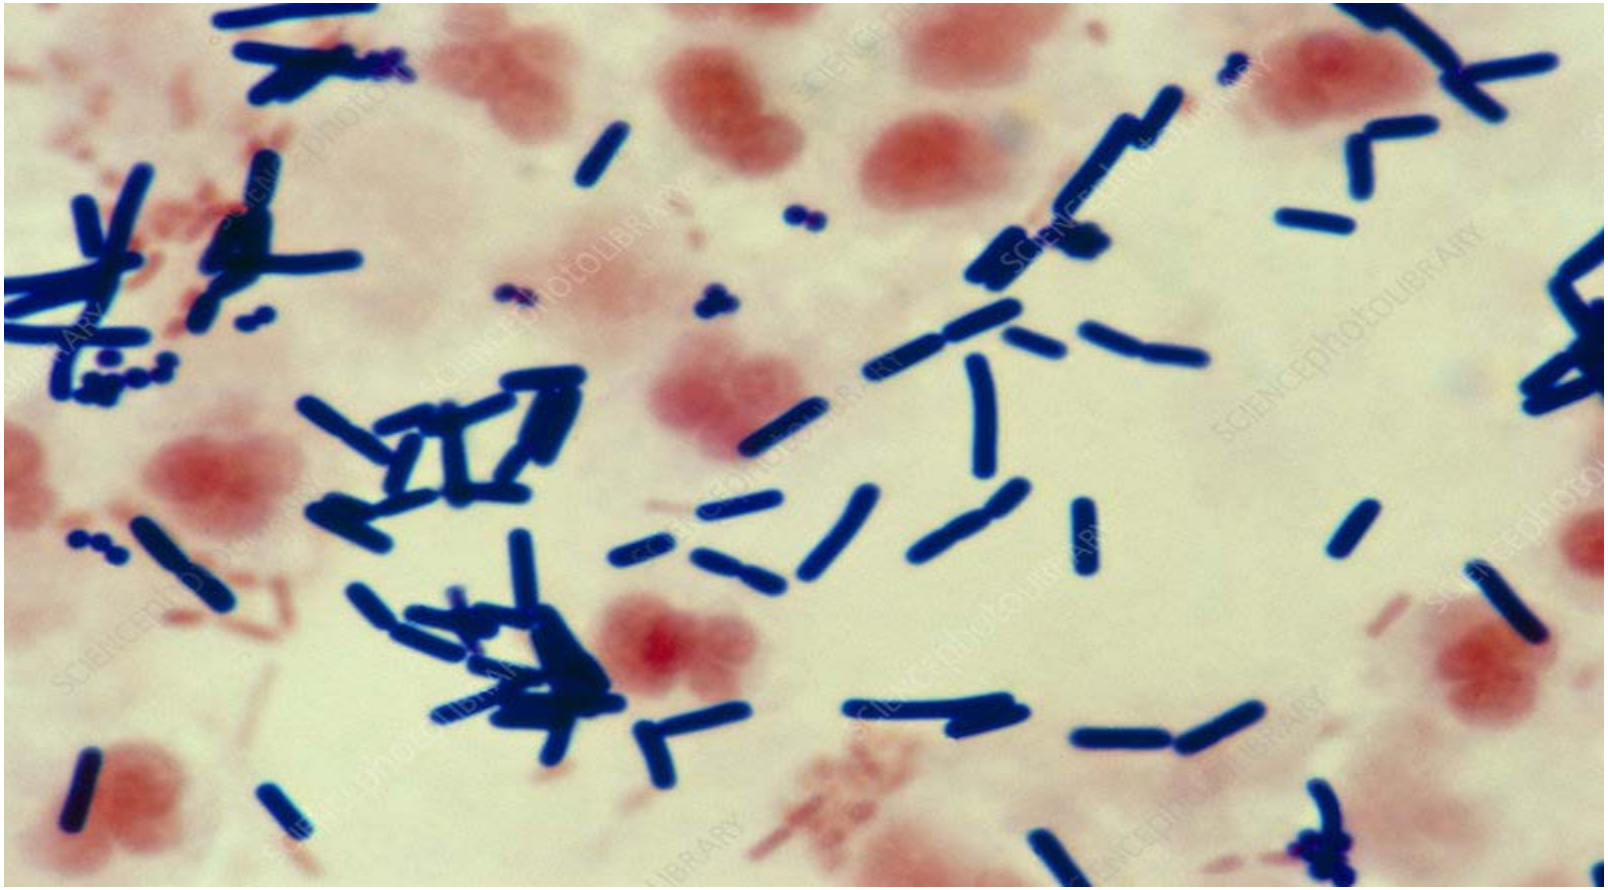
2.Anaerobic or clostridial cellulitis:

-Clostridiae invade fascial planes(fasciitis) with minimal toxin production but no invasion of muscle tissue.

-Lesions vary from limited '**gas abscess**' to extensive involvement of limbs.

-Seropurulent discharges with offensive odor produced

Cl.Perfringes from wound



3.Anaerobic myositis or myonecrosis or gas gangrene

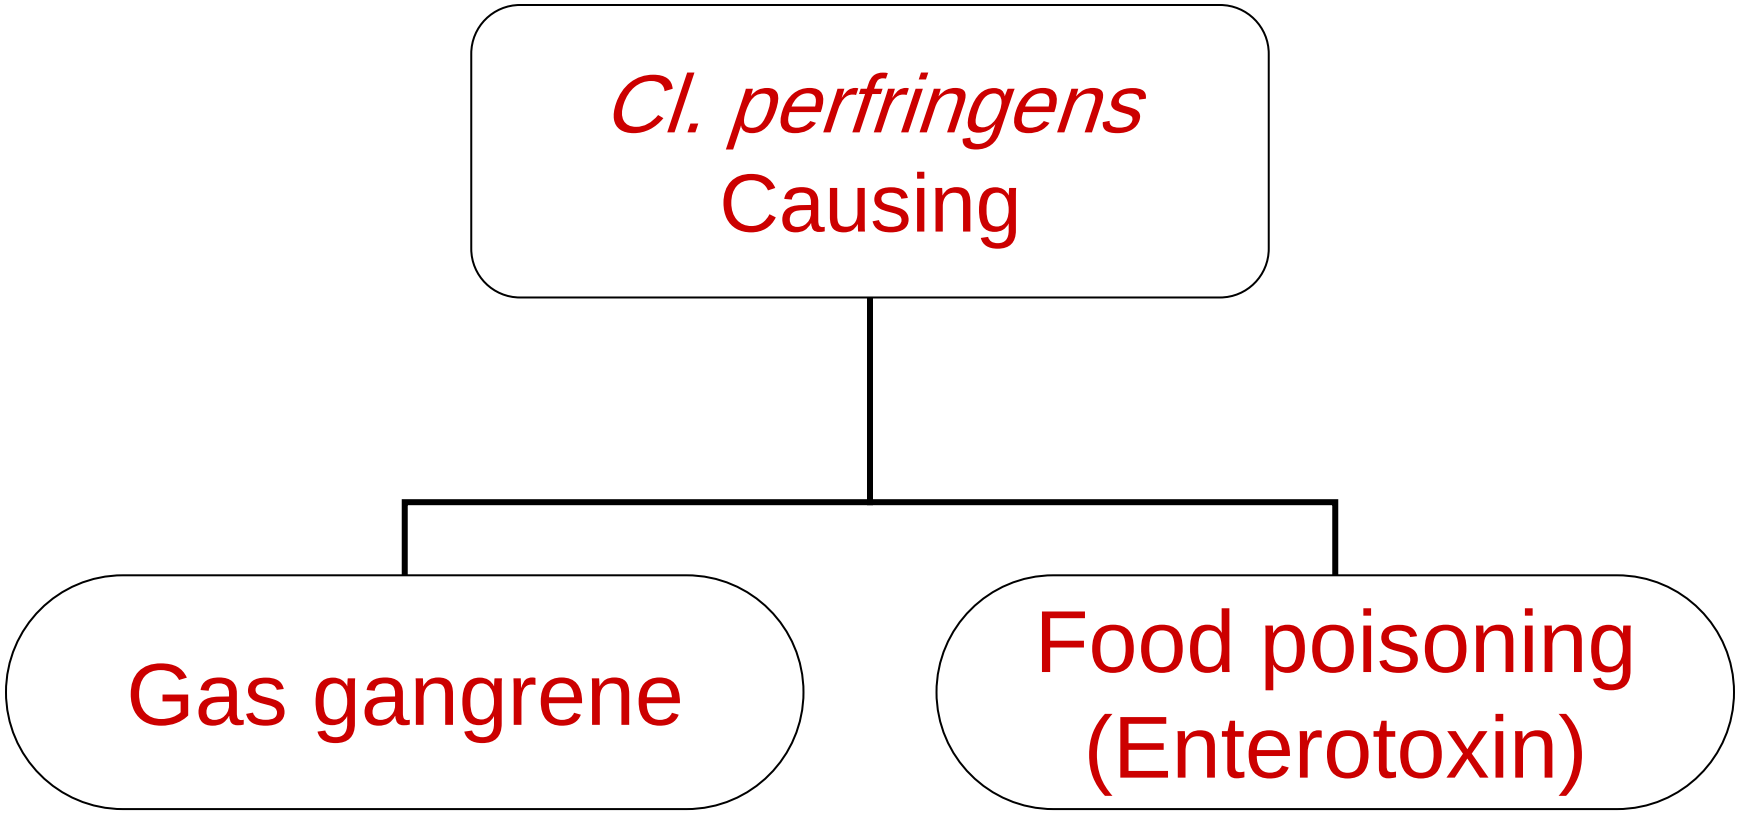
-Most serious complication of clostridial invasion of healthy muscle tissue .

-Abundant formation of exotoxin & production of gas.

-GG is disease of war. In civilian life it follows road accidents or injuries with crushing of muscle mass.

-GG is rarely infection of single clostridium; several species found in association with anaerobic streptococci & facultative anaerobes (*E.coli,Stap,Proteus*)

-Among pathogenic clostridiae,*Cl.perfringens* is most frequently encountered(60%) followed by *Cl.Novyi* & *Cl.septicum*(20-40%).



Cl. perfringens
Causing
Gas gangrene
Food poisoning
(Enterotoxin)

Toxins

- **The toxins of *Cl. perfringens***
  - **1- α toxin** (phospholipase C, lecithinase) is the most important toxin
    - Lyses of RBCs, platelets, leucocytes and endothelial cells
    - Increased vascular permeability with massive hemolysis and bleeding tissue destruction
    - Hepatic toxicity and myocardial dysfunction
  - **2- β-toxin** is responsible for necrotic lesions in necrotizing enterocolitis
  - **3- Enterotoxin** is heat labile toxin produced in colon food poisoning

Laboratory diagnosis •

CULTURAL CHARACTERISTICS

-**Robertson's cooked meat broth** is ideal; meat is turned **pink but not digested** with sour odor.

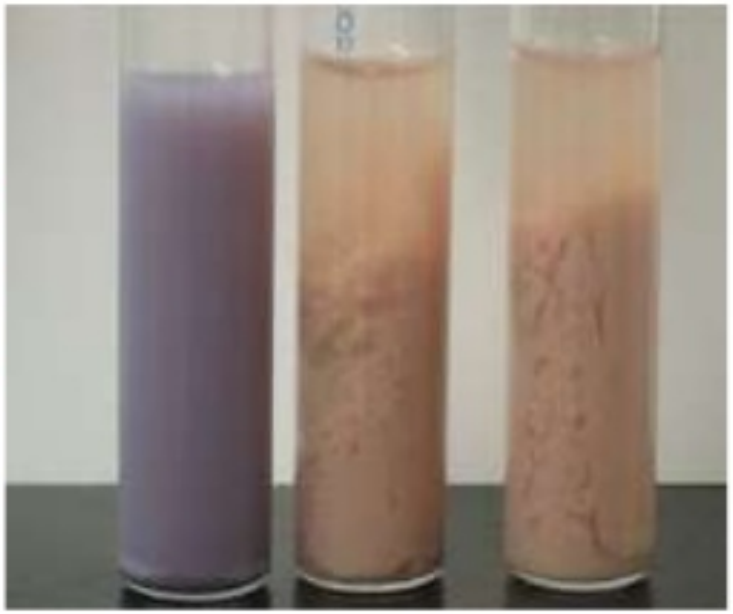
-**Stormy fermentation** of lactose in litmus milk; the acid coagulates casein-**acid clot.**

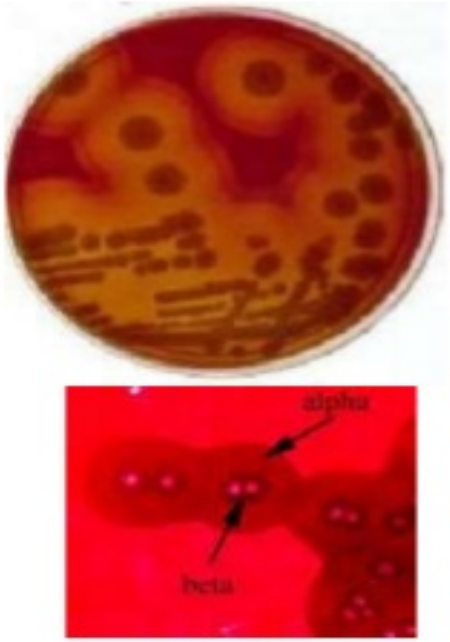
-**On BAM**: Target haemolysis

BIOCHEMICAL REACTIONS:

Glucose		Indole	-ve
Lactose	Fermented with	MR	+ve
Maltose	A & G production	VP	-ve

-H_2S prodn. test & Nitrate redn. test - +ve





Left to right:

a. **RCM:** Meat turned pink but not digested
b. **Litmus Milk:** Stormy fermentation & acid clot in Litmus milk
c. **BAM:** Target hemolysis

Nagler’s Reaction

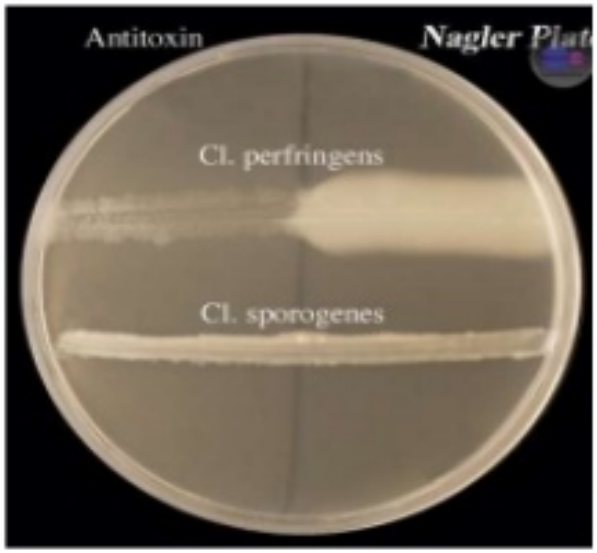
- *C. perfringens* can be diagnosed by Nagler's reaction, in which the suspect organism is cultured on an egg yolk media plate(contains lecithin).
- . One side of the plate contains anti-alpha-toxin, while the other side does not. A streak of suspect organism is placed through both sides. An area of turbidity will form around the side that does not have the anti-alpha-toxin, indicating uninhibited lecithinase activity.

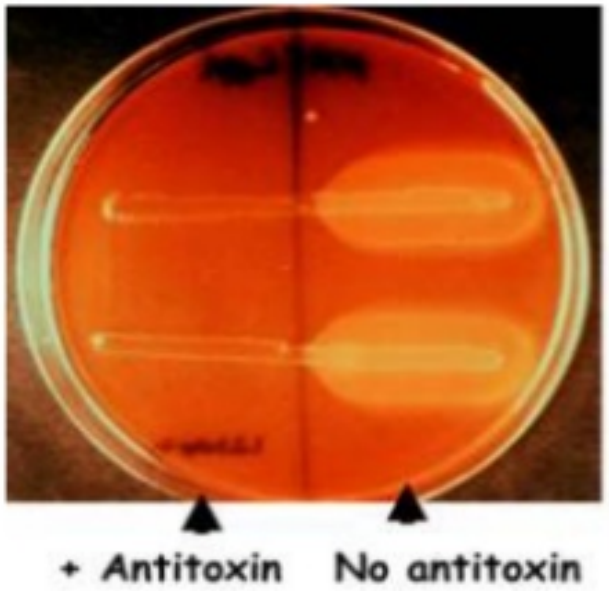
4.Nagler's Reaction

-Rapid detection of *Cl.perfringens* from clinical sample

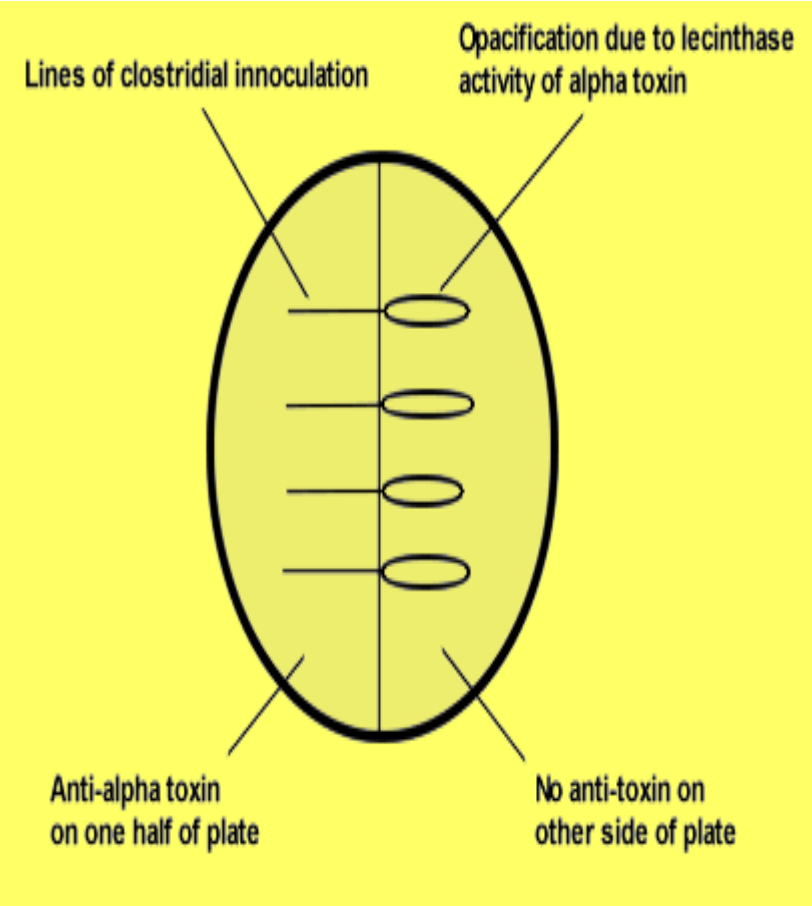
-Done to detect the **lecithinase** activity of **alpha toxin**

-Characteristics **opalescence is produced** around colonies in **+ve test** due to breakdown of lipoprotein complex in the medium

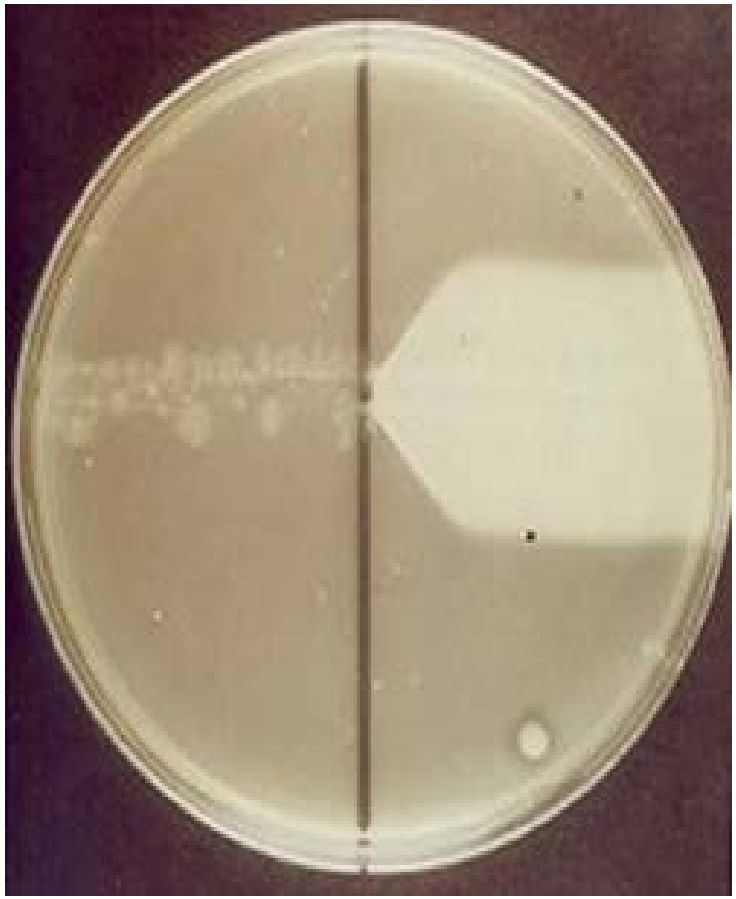




Nagler Reaction



Procedure of Nagler Reaction



Positive Nagler Reaction

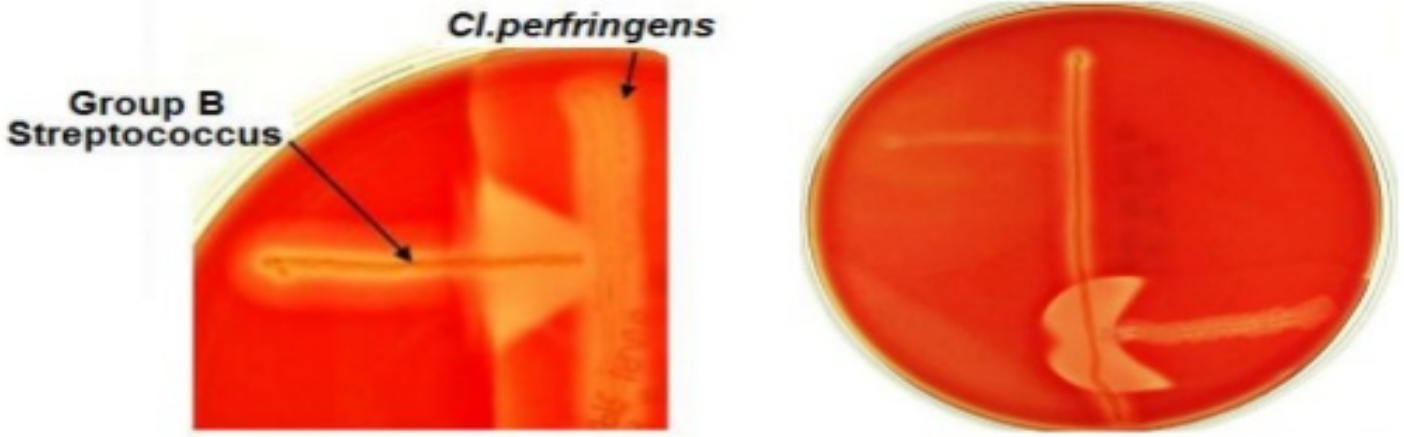
C. perfringens Nagler Reaction

NOTE: Lecithinase (α-toxin; phospholipase) hydrolyzes phospholipids in egg-yolk agar around streak on right. Antibody against α-toxin inhibits activity around left streak.

5.Reverse CAMP Test:

-Used for differentiation of *Cl.perfringens* from other clostridium species.

-CAMP +ve Group B Streptococcus is streaked in SBA & *Cl.perfringens* is streaked perpendicular to it "**arrowhead**"(enhanced) hemolysis is seen between growth of *Cl.perfringens* & Group B streptococcus



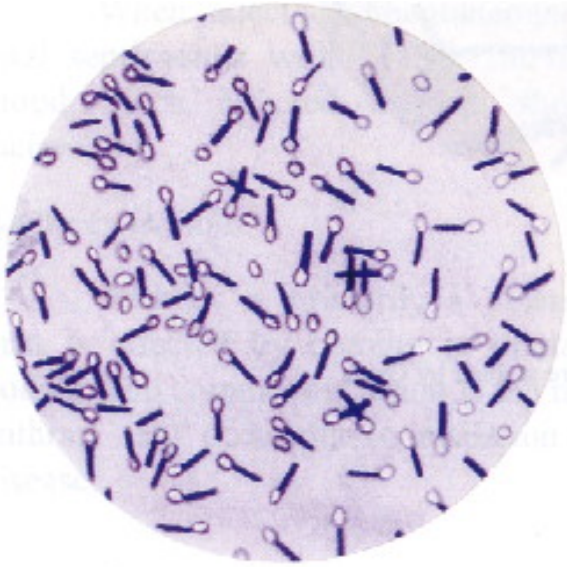
Clostridium tetani

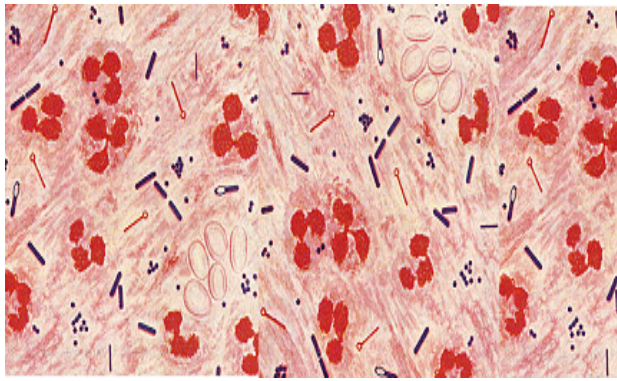
- *Cl.tetani* is widely distributed in soil & in intestine of human beings & animals.

- They cause tetanus. Tetanus is a medical condition characterised by prolonged contraction of skeletal muscle fibres in both man & animal.

Clostridium tetani

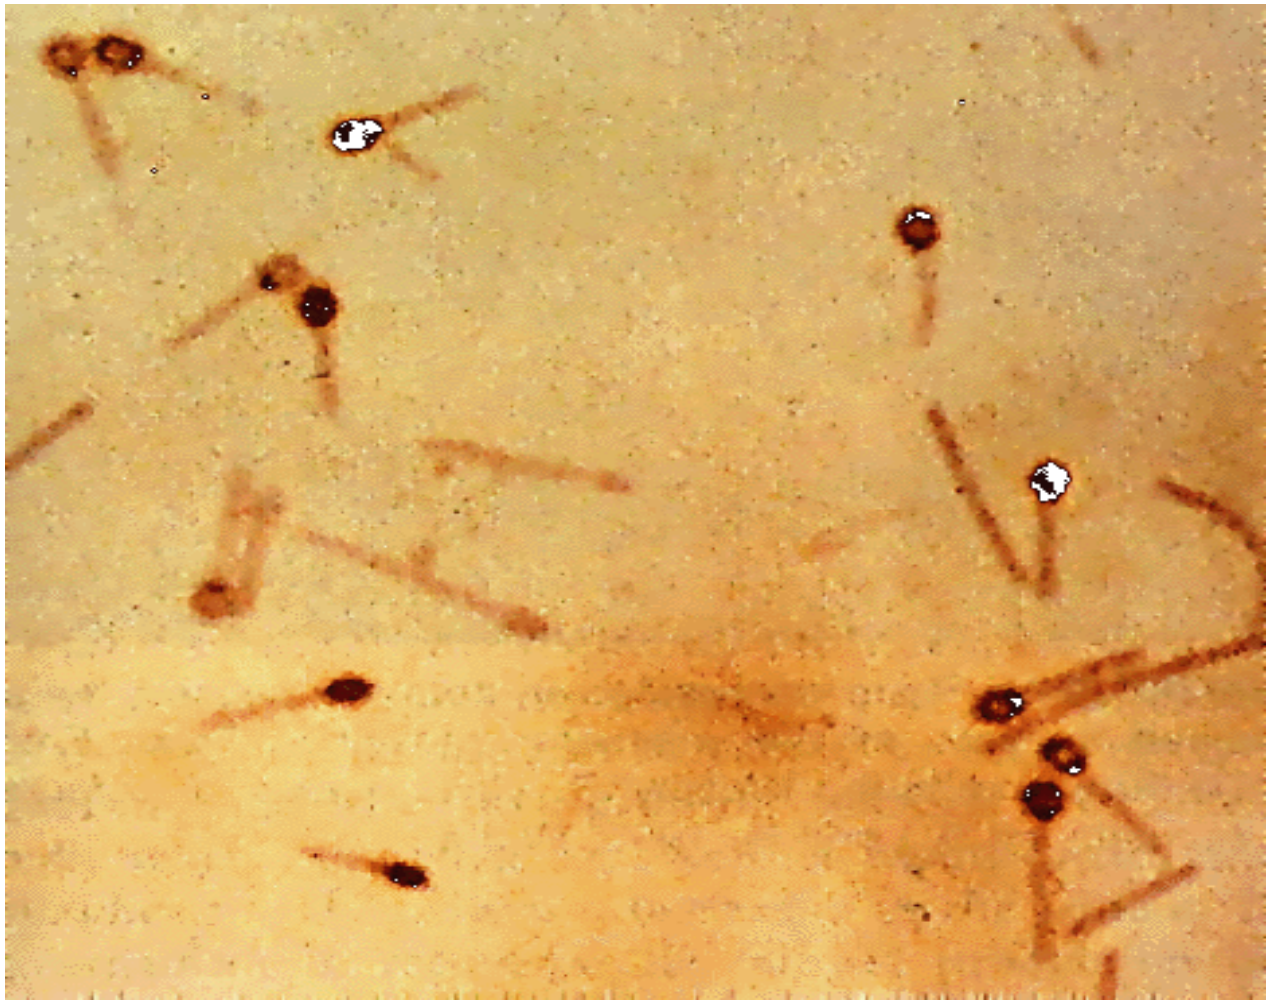
- **Morphology .**
- Gram positive, straight, slender rod with rounded ends
- All species form endospore (drumstick with a large round end)
- Fermentative
- Obligate anaerobe
- Motile by peritrichous flagella
- Grows well in cooked meat broth and produces a thin spreading film when grown on enriched blood agar
- Spores are highly resistant to adverse conditions
- Iodine (1%) in water is able to kill the spores within a few hours.





Clostridium tetani

Clostridium tetani Gram Stain

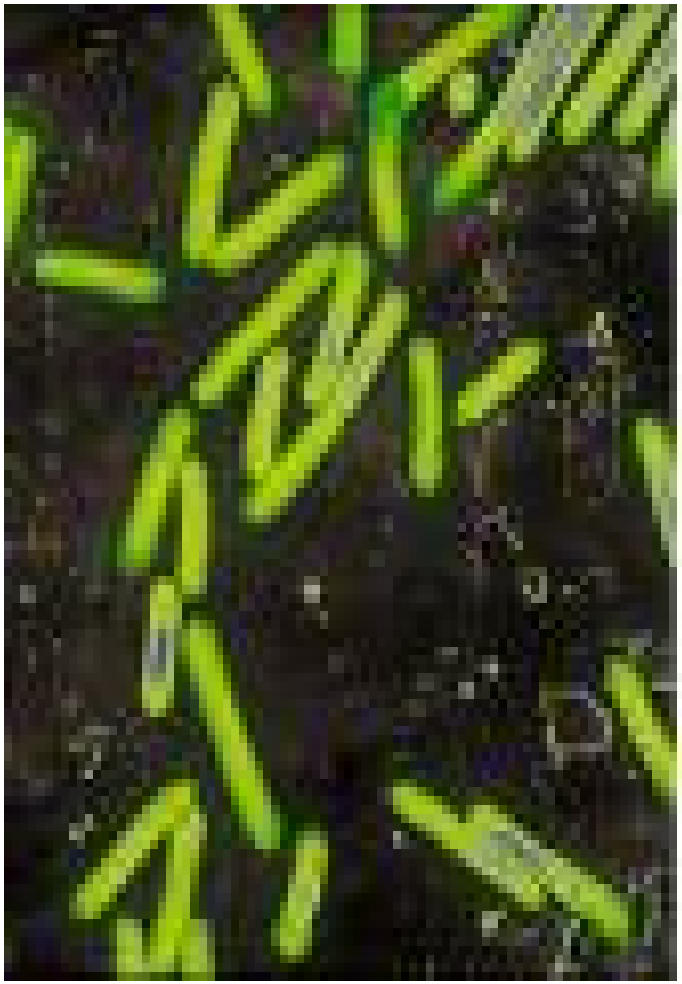


NOTE: Round terminal spores give cells a "drumstick" or "tennis racket" appearance.

Spore

- The spores are spherical, terminal giving the bacillus the characteristic ‘drumstick’ appearance.

- Morphology depends on stage of development. Young spore may be oval rather than spherical.



Toxins

- *Cl. tetani* produces two types of toxins:
  - **1- Tetanolysin**, which causes lysis of RBCs.
  - **2- Tetanospasmin** is neurotoxin and essential pathogenic product.
    - Tetanospasmin is toxic to humans and various animals when injected parenterally, but it is not toxic by the oral route.
    - Tetanospasmin which causes increasing excitability of spinal cord neurons and muscle spasm

Risus Sardonicus in Tetanus Patient

Cultural characteristics

- 1.Robertson's cooked meat medium: turbidity & some gas formation. The meat is not digested but turns black on prolonged incubation.
- 2.Blood agar: fine translucent film of growth.α hemolysis is produced, which later develops into β hemolysis, due to the production of hemolysin (tetanolysin).

Biochemical reactions

- Forms indole.
- MR & VP negative.
- H_2S is not formed.
- Nitrates are not reduced.
- Gelatin liquefaction-slow.
- Greenish fluorescence produced on media containing neutral red.

Thank you•

Microbiology

Introduction

Microbiology is study of microorganisms, or microbes, a huge diverse group of generally minute (too small to be seen by naked eye) simple life-forms, include: bacteria, archaea, algae, fungi, protozoa, and viruses.

The field is concerned with the structure, function, and classification of such organisms and with ways of both exploiting and controlling their activities.

This field study includes basic microbial research, research on infectious diseases, study of prevention and treatment of disease, environmental functions of microorganisms, and industrial use of microorganisms for commercial, agricultural, and medical purposes.

Microorganisms are either unicellular, multicellular or acellular living organisms. And are either **Eukaryotes** or **Prokaryotes**.

-Eukaryotes; whose cells have a nucleus and organelles (e.g. mitochondria) enclosed within membranes, may also be multicellular and include organisms consisting of many cell types forming different kinds of tissue.

-Prokaryotes is a unicellular organism that lacks nucleus, mitochondria, or any other organelle. All the intracellular components (proteins, DNA and metabolites) are located together in the cytoplasm enclosed by the cell membrane, rather than in separate cellular compartments.

-Viruses are acellular microorganisms metabolically inert organisms and therefor replicate only within living cells.

They are included in microbiology because of their small size, their close relationship with cells, and their involvement in numerous infectious diseases.

Most microorganisms are measured in micrometers, with two exceptions. The **helminths** are measured in millimeters, and the **viruses** are measured in nanometers.

Microorganisms are essential to the operation of the earth's ecosystems, as photosynthesizers, decomposers, and recyclers

Microbiologists have identified the causative agents for over 2,000 infectious diseases. Some infectious diseases are currently emerging and reemerging. These are on the rise because of rapid travel, the opening up of undeveloped geographic areas, questionable agricultural practices and food handling, drug resistance, and increases in people with chronic medical conditions.

BACTERIA (bacterium)

Bacteria are microscopic single-celled prokaryotic microorganisms that thrive in diverse environments. Typically a few micrometres in length, bacteria have a number of shapes , ranging from spheres to rods and spirals. Bacteria inhabit soil, water, acidic hot springs, radioactive waste, and the deep portions of Earth's crust. Bacteria also live in symbiotic and parasitic relationships with plants and animals. There are typically 40 million bacterial cells in a gram of soil and a million bacterial cells in a milliliter of fresh water.

Bacteria are vital in recycling nutrients, with many of the stages in nutrient cycles such as the fixation of nitrogen from the atmosphere and putrefaction. There are approximately ten times as many bacterial cells in the human flora as there are human cells in the body, with the largest number of the human flora being in the gut flora, and a large number on the skin. The vast majority of the bacteria in the body are rendered harmless by the protective effects of the immune system, and some are beneficial. However, several species of bacteria are pathogenic and cause infectious diseases, including **cholera** (*Vibrio chlera*e),syphilis(*Treponema pallidum*), **anthrax**(*Bacillus anthra*cis) **leprosy** (*Mycobacterium leprae*) and **plague**(*Yersinia pestis*) , The most common fatal bacterial diseases are respiratory infections, with tuberculosis(*Mycobacterium tuberculosis*) alone killing about 2 million people a year ,mostly in Africa. In

developed countries, antibiotic care used to treat bacterial infections and are also used in farming, making antibiotic resistance a growing problem. In industry, bacteria are important in sewage treatment and the break down of oil spills, the production of cheese and yogurt through fermentation, and the recovery of gold, palladium, copper and other metals in the mining sector, as well as in biotechnology, and the manufacture of antibiotics and other chemicals.

Bacterial Morphology

Bacteria display a wide diversity of shapes and sizes. Bacterial cells are about one-tenth the size of eukaryotic cells and are typically 0.5– 5.0 micrometers in length.

Bacteria can be classified by direct examination with the light microscope according to their morphology and arrangement.

Most bacterial shaped (Fig.1) are either:
1-Spherical (coccus),
2-Rod shaped with round-ended cylinders (bacillus) (e.g. *Staphylococus aureus*).
3- Slightly curved rods or comma-shaped (vibrio) (e.g. *Bacillus anthracis*).
4- Spiral-shaped, called **spirilla** (e.g *Helicobacter pylori*)
5-Tightly coiled, called **spirochaetes** (e.g.*Treponema pallidum*) .
6- A small number of species even have tetrahedral or cuboidal shapes , branching filamentous types with a star-shaped (e.g. *Nocardia sp.)*.

This wide variety of shapes is determined by the bacterial cell wall and cytoskeleton, and is important because it can influence the ability of bacteria to acquire nutrients, attach to surfaces, swim through liquids and escape predators.
Shape and arrangement (Fig.1) of cells are key means of describing bacteria. Arrangements of cells are based on the number of planes in which a given cell

type divides. Cocci can divide in many planes to form pairs (diplococci) (*Streptococcus pneumonia*) , chains (streptococci), packets (sarcinae), or clusters (micrococci or staphylococci). Bacilli divide only in the transverse plan. If they remain attached, they form pairs, chains, or palisades arrangements.

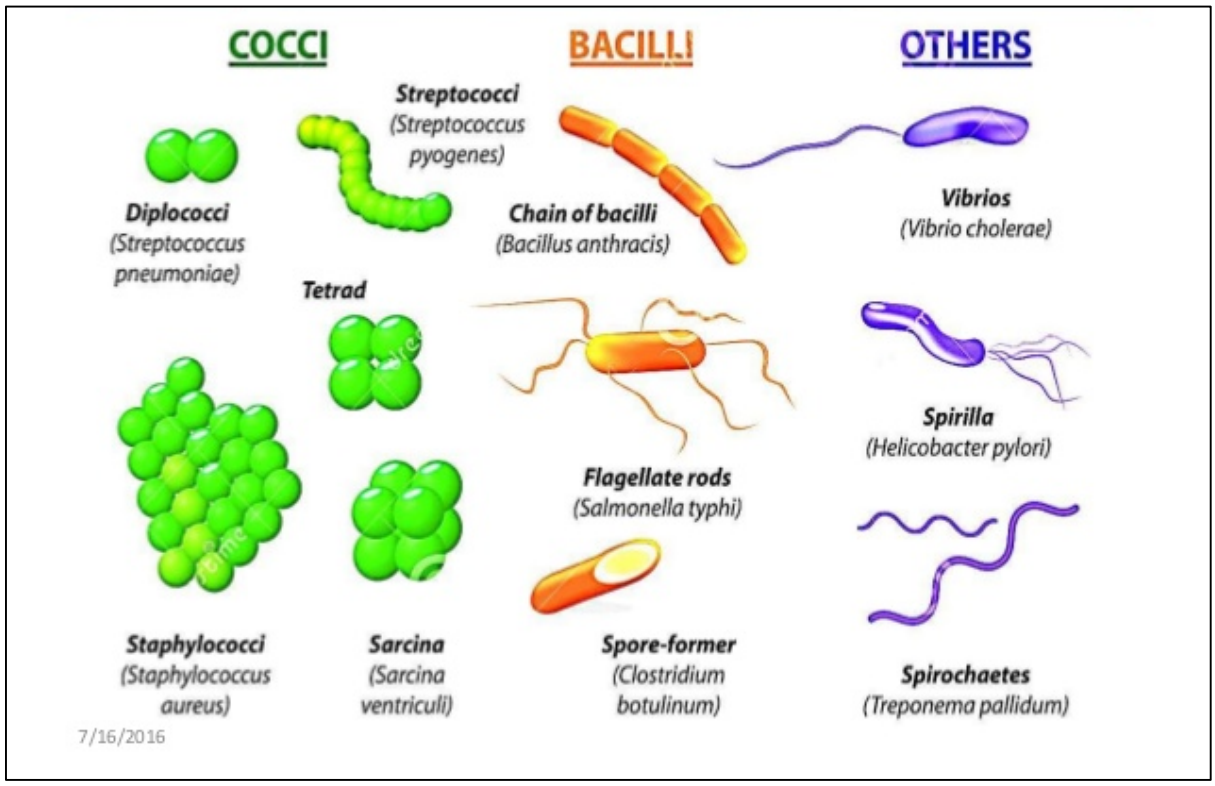

Figure 1: shapes and arraignments of bacterial cells.

Cell wall

organisms, the bacterial cell wall provides structural integrity to the cell. In prokaryotes, the primary function of the cell wall is to protect the cell from internal turgor pressure caused by the much higher concentrations of proteins and other molecules inside the cell compared to its external environment. The bacterial cell wall differs from that of all other organisms by the presence of peptidoglycan which is located immediately outside of the cytoplasmic membrane. Peptidoglycan is made up of a polysaccharide backbone consisting of alternating N-Acetylmuramic acid (NAM) and N-acetylglucosamine (NAG) residues in equal amounts. Peptidoglycan is responsible for the rigidity of the bacterial cell wall and for the determination of cell shape. It is relatively porous and is not considered to be a permeability barrier for small substrates. While most of bacterial cell walls contain peptidoglycan, not all cell walls have the same overall structures. There are two main types of bacterial cell walls, those of gram-positive bacteria and those of gram-negative bacteria, which are differentiated by their Gram staining characteristics.

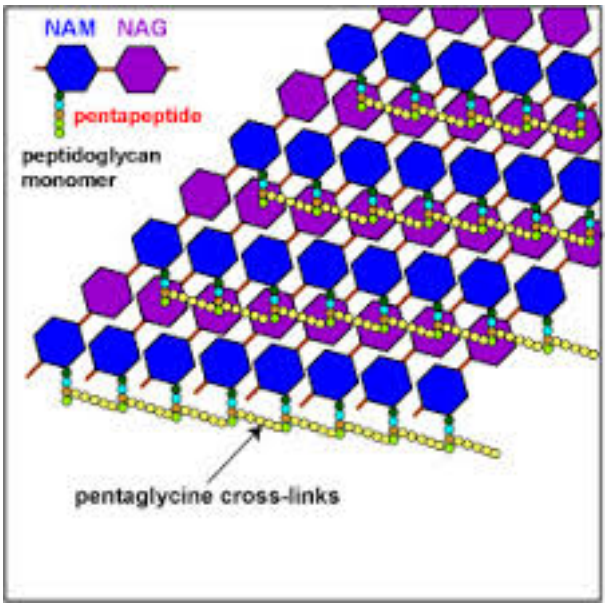

Figure.2 . Peptidoglycan structure

The gram-positive cell wall

Gram-positive cell walls (Its bacteria stained as purple colour) are thick and the peptidoglycan layer constitutes almost 95% of the cell wall in some gram-positive bacteria. It also contains teichoic acid directly attached to the peptidoglycan and lipoteichoic acidic. There are two main types of teichoic acid: ribitol teichoic acids and glycerol teichoic acids. The latter one is more widespread. These acids are polymers of ribitol phosphate and glycerol phosphate, respectively, and only located on the surface of many gram-positive bacteria. However, the exact function of teichoic acid is debated and not fully understood. A major component of the gram-positive cell wall is lipoteichoic acid. One of its purposes is providing an antigenic function. The cell wall of gram-positive bacteria is often pressed tightly against the cell membrane with very little space between them (Fig.3).

The Gram-negative cell wall

Gram-negative cell walls are thin, and unlike the gram-positive cell walls, they composed of an outer membrane (OM) and a thinner shell of peptidoglycan layer adjacent to the cytoplasmic membrane. Gram-negative bacteria are stained as pink colour. The outer membrane contains a unique component, lipopolysaccharide (LPS) in addition to proteins and phospholipids.

The chemical structure of lipopolysaccharides is often unique to specific bacterial sub-species and is responsible for many of antigenic properties of these strains. Lipopolysaccharides, also called (endotoxins), are composed of polysaccharides and lipid A which are responsible for much of the toxicity of Gram-negative bacteria. The lipopolysaccarides are embedded in the membrane(Fig.3).

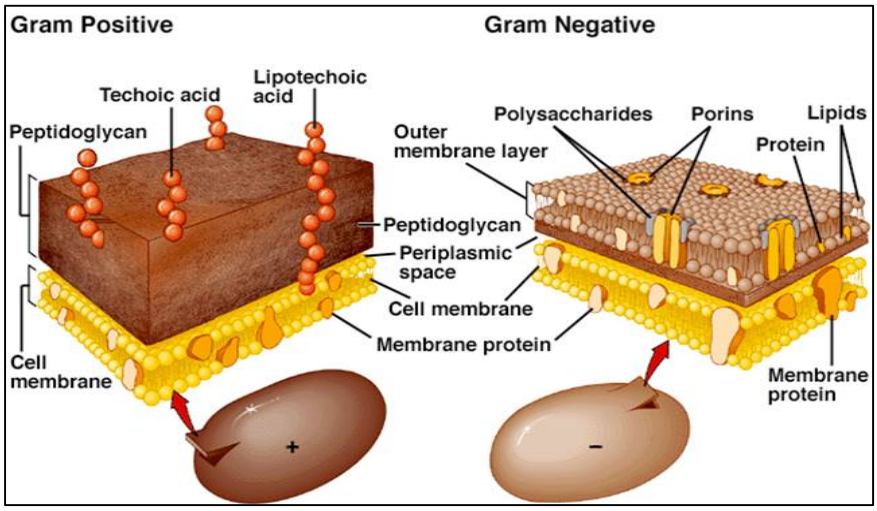

Figure.3 . Gram positive and gram negative cell wall structures

Non typical cell wall

Mycobacterium and Nocardia contain peptidoglycan and stain gram-positive, but their cell wall is composed of unique types of lipids.

One of these is very long chain fatty acid called mycolic acid, or cord factor, that contributes to the pathogenicity of this group.

Mycoplasmas are bacteria that naturally lack a cell wall. Its cell membrane contains sterols that make it resistant to lysis.

Plasma membrane The plasma membrane or bacterial cytoplasmic membrane is composed of a phospholipid bilayer. The General functions of a cell membrane are **acting as a permeability barrier** for most molecules and serving as the location for the **transport of molecules** into the cell and **energy conservation** . However, channels called porins are present in the outer membrane that allow for passive transport of many ions, sugars and amino acids across the outer membrane. These molecules are therefore present in the periplasm, the region between the cytoplasmic and outer membranes**.**

Cell Extensions and Surface Structures

Bacteria often have accessory **appendages** sprouting from their surfaces. Appendages can be divided into two major groups: those that provide motility (flagella and axial fi laments) and those that provide attachments or channels (fimbriae and pili).

Flagella—Bacterial Propellers

The prokaryotic **flagellum** is provide the power of motility or self-propulsion. This allows a cell to swim freely through an aqueous habitat. The bacterial flagellum when viewed under high magnification displays three distinct parts: the filament, the hook (sheath), and the basal body.

Flagella vary both in number and arrangement according to two general patterns(Fig 4):

(A) In a **polar** arrangement, the flagella are attached at one or both ends of the cell.

Three subtypes of this pattern are:

1-monotrichous * with a single flagellum.

2- **amphitrichous *** with flagella at both poles of the cell.

3- **lophotrichous *** with small bunches or tufts of flagella emerging from the same site.

(B) In a **peritrichous *** arrangement, flagella are dispersed randomly over the surface of the cell. The presence of motility is one piece of information used in the laboratory identification of various groups of bacteria. Special stains or electron microscope preparations must be used to see arrangement, because flagella are too minute to be seen in live preparations with a light microscope.

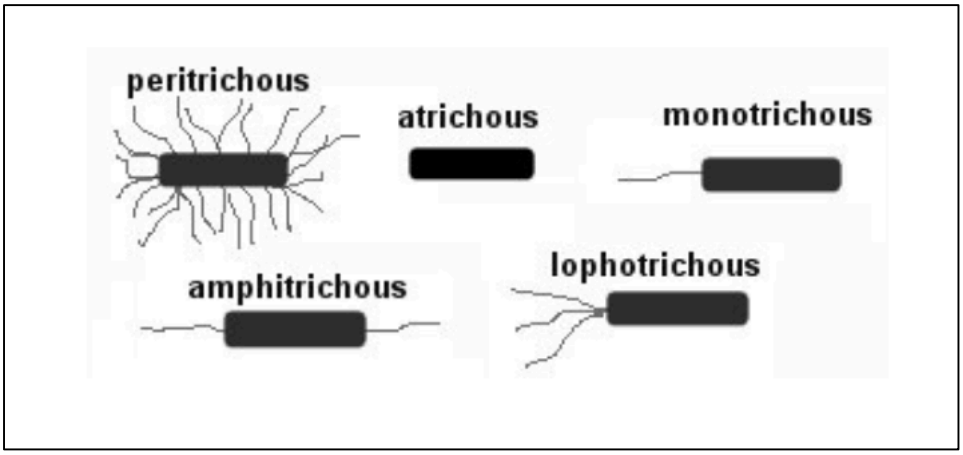

Figure 4. Flagella types.

Fimbriae and Pili

The structures termed **fimbria** and **pilus** both refer to bacterial surface appendages that are involved in interactions with other cells but do not provide locomotion, except for some specialized pili.

Fimbriae are small, bristle like fibers emerging from the surface of many bacterial cells **.** Compose of protein. Fimbriae have an **inherent tendency** to stick to each other and to surfaces. They may be responsible for the mutual clinging of cells that leads to **biofilms** and other thick aggregates of cells on the surface of liquids and for the microbial colonization of inanimate solids such as, teeth, rocks and glass. Some pathogens can colonize and infect host tissues because of a tight adhesion between their fimbriae and epithelial cells **.** For example, the gonococcus (agent of gonorrhea) colonizes the genitourinary tract, and *Escherichia coli* colonizes the intestine by this means.

Pilus (also called a *sex pilus*) is an elongate, rigid tubular structure made of a special protein, *pilin* . So far, true pili have been found only on gram-negative bacteria, where they are utilized primarily in conjugation which involves a transfer of DNA from one cell to another A pilus from a donor cell unites with a recipient cell, thereby providing a connection for making the transfer (Fig 5).

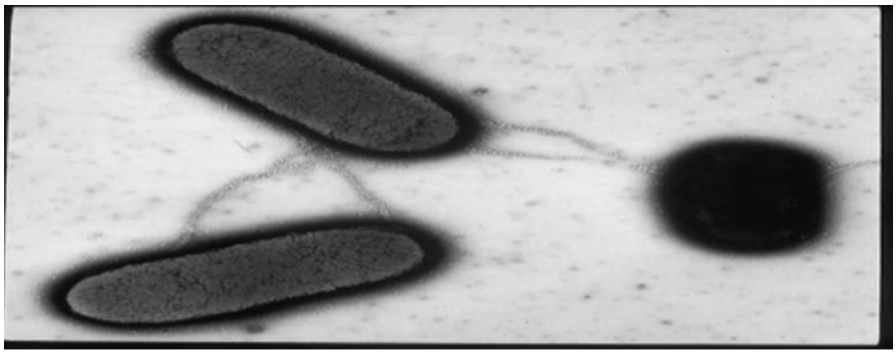

Fig.5.Three bacteria in the process of conjugating

Biofilms:- A **biofilm** comprises any syntrophic consortium of microorganisms in which cells stick to each other and often also to a surface. These adherent cells become embedded within a slimy extracellular matrix that is composed of extracellular polymeric substances (EPS). The cells within the biofilm produce the EPS components, which are typically a polymeric conglomeration of extracellular polysaccharides, proteins, lipids and DNA.

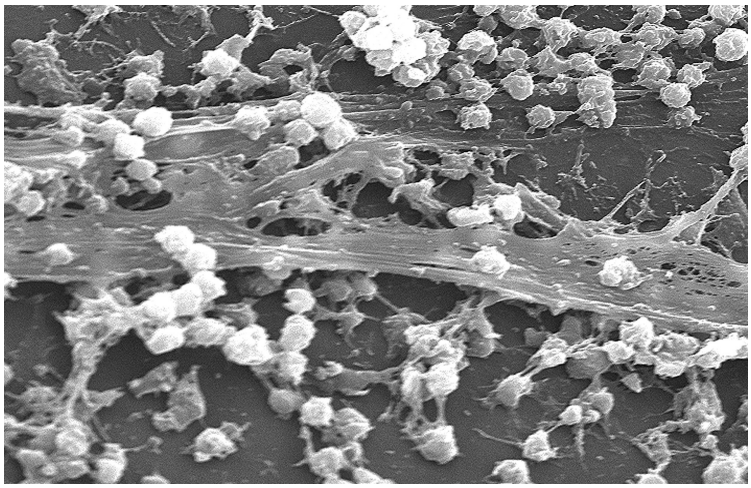

Figure 6. Biofilm

Biofilms may form on living or non-living surfaces and can be prevalent in natural, industrial and hospital settings (Fig.7). The microbial cells growing in a biofilm are physiologically distinct from planktonic cells of the same organism, (single-cells that may float or swim in a liquid medium). Biofilms can form on the teeth of most animals as dental plaque, where they may cause tooth decay and gum disease.

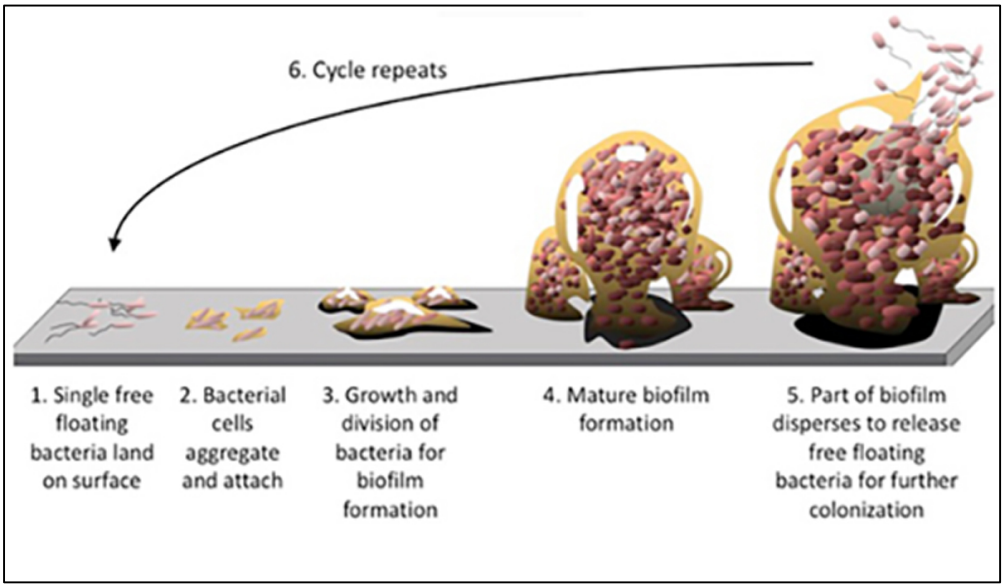

Figure 7. Five stages of biofilm development

Glycocalyx (slime layer)

The glycocalyx is a loose shield of polysaccharide coating that covers the outer surface of many bacteria, protects them from dehydration and loss of nutrients and allows bacteria to adhere firmly to the various structures, e.g. oral mucosa, teeth, heart, and catheters, and contribute to the formation of biofilms.

Capsule

An amorphous, gelatinous layer (usually more substantial than the glycocalyx) surrounds the entire bacterium. It composed of polysaccharides and sometimes proteins. The sugar components of the polysaccharides vary in different bacterial and frequently determine the serological type within a species.

Contents of the Cell Cytoplasm (Fig.8)

Bacterial Chromosomes and Plasmids:

The hereditary material of most bacteria exists in the form of a single circular strand of DNA designated as the **bacterial chromosome.** By definition, bacteria do not have a true nucleus. Their DNA is not enclosed by a nuclear membrane but instead is aggregated in a central area of the cell called the **nucleoid.** The chromosome is actually an extremely long molecule of DNA that is tightly coiled to fit inside the cell compartment. Arranged along its length are genetic units (about 2000 genes) that carry information required for bacterial maintenance and growth. many bacteria contain other, nonessential pieces of DNA called plasmids.

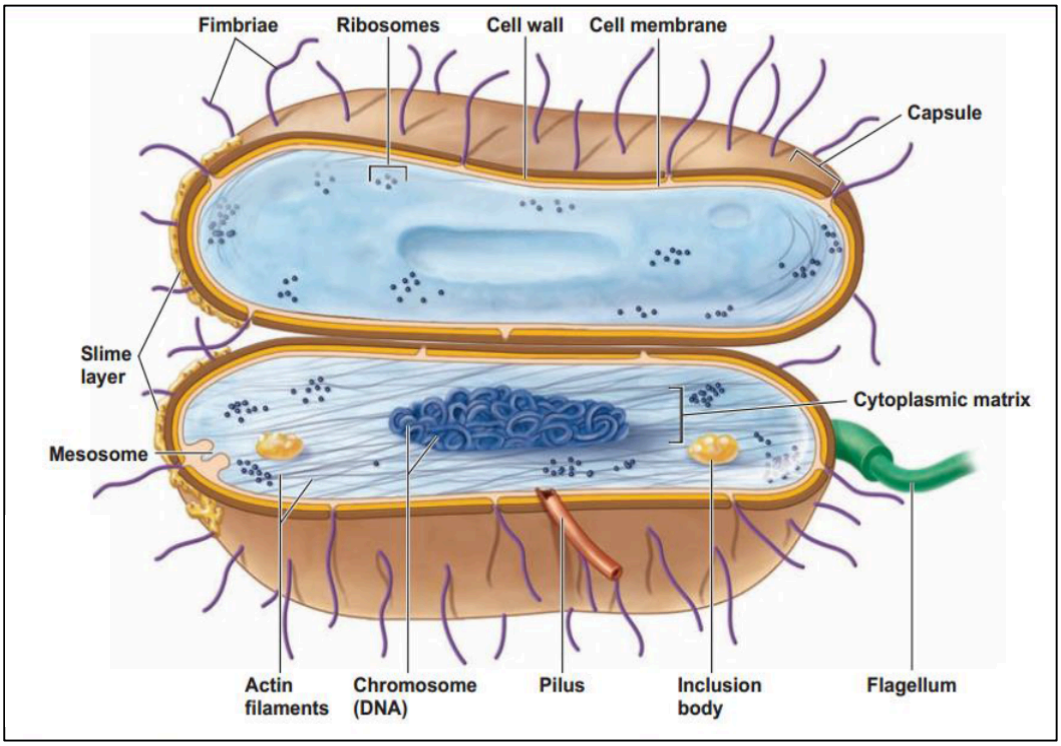

Figure 8. 3D structure of the bacterial cell.

Plasmids

A **plasmid** is a small DNA molecule within a cell that is physically separated from a chromosomal DNA and can replicate independently. They are most

commonly found as small circular, double-stranded DNA molecules in bacteria; however, plasmids are sometimes present in archaea and eukaryotic organisms. In nature, plasmids often carry genes that may benefit the survival of the organism, for example antibiotic resistance.

Ribosomes: Sites of Protein Synthesis

A bacterial cell contains thousands of **ribosomes,** which are made of RNA and protein., ribosomes show up as fine, spherical specks dispersed throughout the cytoplasm that often occur in chains (polysomes). Many are also attached to the cell membrane. Chemically, a ribosome is a combination of a special type of RNA called ribosomal RNA, or rRNA (about 60%), and protein (40%). They fit together to form factory" where protein synthesis occurs.

Inclusions, or Granules: Storage Bodies

Inclusion bodies, sometimes called **elementary bodies**, are nuclear or cytoplasmic aggregates of stable substances, usually proteins.

Some inclusion bodies contain condensed, energy-rich organic substances, such as glycogen and poly b-hydroxybutyrate (PHB), within special single-layered membranes. Other called **granules,** contain crystals of inorganic compounds and are not enclosed by membranes.

Bacterial Endospores:

Resistant Life Form

An **endospore** is a dormant, tough, and non-reproductive structure produced by certain bacteria for withstanding hostile conditions and facilitating survival. (e.g. endospores produced by *Bacillus, Clostridium)*. These bacteria have a two-phase life cycle that shifts between a **vegetative cell** and an **endospore.** The vegetative cell is the metabolically active and growing phase. When exposed to certain environmental signals, it forms an endospore by a process termed **sporulation.** The spore exists in an inert, resting condition that is capable of high resistance

and very long-term survival. The spore contains bacterial DNA, a small amount cytoplasm, cell membrane, peptidoglycan, very little water and a thick keratin like coat. This coat is remarkably resistant to heat, dehydration, radiation and chemicals. Once formed, the spore is metabolically inert, and can remain dormant for many years. Bacterial endospores can called either terminal or subterminal spores depending on their position inside the bacterial cell. When appropriate conditions supervene (e.g. water, nutrients), there is enzymatic degradation of the coat, and the spore transforms into a metabolizing, reproducing bacterial cell once again (Fig.9).

Medical Significance of Bacterial Spores

The clinical lies in their extraordinary resistance to heat and chemicals. Because of this, sterilization cannot be easily achieved by boiling; other more efficacious methods of sterilization, such as steam under pressure (autoclaving), are required to ensure the sterility of products used for medical surgical or microbiological purposes.

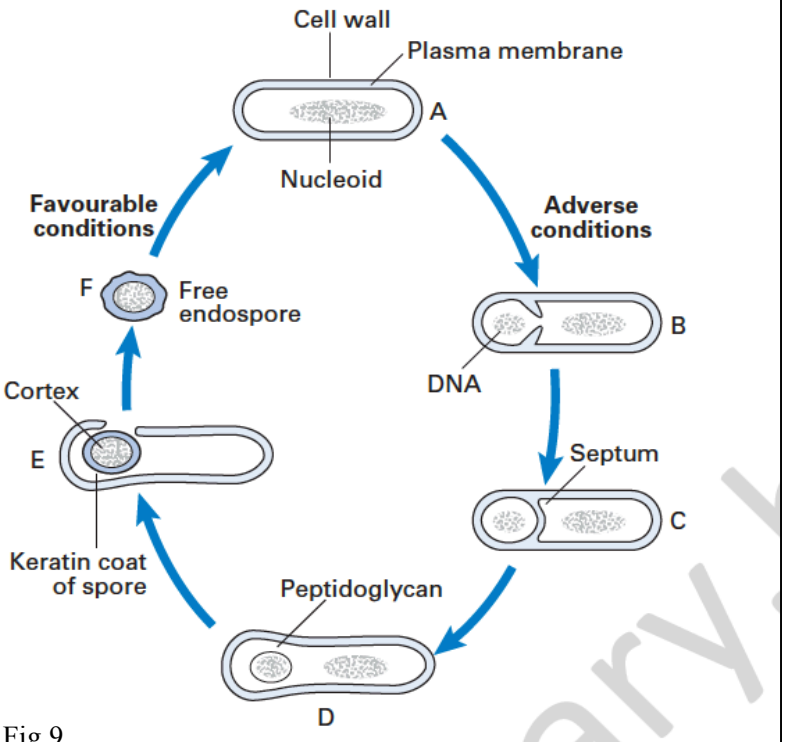

Fig.9 The cycle of sporulation. (**A**) Vegetative cell; (**B**) ingrowth of cytoplasmic membrane; (**C**) developing forespore; (**D**) forespore completely cut off from the cell cytoplasm; (**E**) development of cortex and keratin spore coat; (**F**) liberation of spore and conversion to vegetative state under favourable conditions
