Introduction

The molecular spectroscopy is the study of the interaction of electromagnetic waves and matter. The scattering of sun's rays by raindrops to produce a rainbow and appearance of a colorful spectrum when a narrow beam of sunlight is passed through a triangular glass prism are the simple examples where white light is separated into the visible spectrum of primary colors. This visible light is merely a part of the whole spectrum of electromagnetic radiation, extending from the radio waves to cosmic rays. All these apparently different forms of electromagnetic radiations travel at the same velocity but characteristically differ from each other in terms of frequencies and wavelength (Table 1).

Table 1: The electromagnetic spectrum

Radiation type	Wave length λ , (Å)	Frequency $\nu = c / \lambda$, (Hz)	Applications
radio	10^{14}	3×10^4	
Nuclear magnetic resonance	10^{12}	3×10^6	
Television	10^{10}	3×10^8	Spin orientation
Radar	10^8	3×10^{10}	
Microwave	10^7	3×10^{11}	Rotational
Far infrared	10^6	3×10^{12}	Vibrational
Near infrared	10^4	3×10^{14}	
Visible	8×10^3 - 4×10^3	3.7×10^{14} - 7.5×10^{14}	
Ultraviolet	3×10^3	1×10^{15}	Electronic
X-rays	1	3×10^{18}	
Gamma rays	10^{-2}	3×10^{20}	Nuclear transitions
Cosmic rays	10^{-4}	3×10^{22}	

The propagation of these radiations involves both electric and magnetic forces which give rise to their common class name electromagnetic radiation. In spectroscopy, only the effects associated with electric component of electromagnetic wave are important. Therefore, the light wave traveling through space is represented by a sinusoidal trace (figure 1). In this diagram λ is the wavelength and distance A is known as the maximum amplitude of the wave. Although a wave is frequently characterized in terms of its wavelength λ , often the terms such as wavenumber ($\bar{\nu}$), frequency (ν), cycles per second (cps) or hertz (Hz) are also used.

Figure 1: Wave like propagation of light (λ = wavelength , A = amplitude)

The unit commonly used to describe the wavelength is centimeters (cm), the different units are used to express the wavelengths in different parts of the electromagnetic spectrum. For example, in the ultraviolet and visible region, the units use are angstrom (\AA) and nanometer (nm). In the infrared region, the commonly used unit is wavenumber ($\bar{\nu}$), which gives the number of waves per centimeter. Thus

$$1 \text{ cm} = 10^7 \text{ nm} = 10^8 \text{ \AA}$$

$$1 \text{ \AA} = 10^{-1} \text{ nm} = 10^{-8} \text{ cm}$$

The four quantities wavelength, wavenumber, frequency and velocity can be related to each other by following relationships

$$\text{Wavelength } (\lambda) = 1 / \bar{\nu} = c / \nu$$

$$\text{Wave-number } (\bar{\nu}) = 1 / \lambda = \nu / c$$

$$\text{Frequency } (\nu) = c / \lambda = c \bar{\nu}$$

$$\text{Velocity } (c) = \nu \lambda = \nu / \bar{\nu}$$

Absorption of Different Electromagnetic radiations by Organic Molecules

In absorption spectroscopy, though the mechanism of absorption of energy is different in the ultraviolet, infrared and nuclear magnetic resonance regions, the fundamental process is the absorption of a discrete amount of energy. The energy required for the transition from a state of lower energy (E_1) to state of higher energy (E_2) is exactly equivalent to the energy of electromagnetic radiation that causes transition.

Figure 2: Energy transition for the absorption of any electromagnetic radiation

$$\therefore E_1 - E_2 = E = h\nu = hc / \lambda$$

Where E is energy of electromagnetic radiation being absorbed, h is the universal Planck's constant, 6.624×10^{-27} erg sec and ν is the frequency of incident light in cycles per second (cps or hertz, Hz), c is velocity of light 2.998×10^{10} cm s⁻¹ and λ = wavelength (cm)

Therefore, higher is the frequency, higher would be the energy and longer is the wavelength, lower would be the energy. As we move from cosmic radiations to ultraviolet region to infrared region and then radio frequencies, we are gradually moving to regions of lower energies.

A molecule can only absorb a particular frequency, if there exists within the molecule an energy transition of magnitude $E = h\nu$

Although almost all parts of electromagnetic spectrum are used for understanding the matter, in organic chemistry we are mainly concerned with energy absorption from only ultraviolet and visible, infrared, microwave and radiofrequency regions.

Ultraviolet – visible spectroscopy (λ 200 - 800 nm) studies the changes in electronic energy levels within the molecule arising due to transfer of electrons from π - or non-bonding orbitals. It commonly provides the knowledge about π -electron systems, conjugated unsaturations, aromatic compounds and conjugated non-bonding electron systems etc.

Infrared spectroscopy ($\bar{\nu}$ 400-4000 cm⁻¹) studies the changes in the vibrational and rotation movements of the molecules. It is commonly used to show the presence or absence of functional groups which have specific vibration frequencies viz. C=O, NH₂, OH, CH, C-O etc.

Nuclear magnetic resonance (radiofrequency ν 60-600 MHz) provides the information about changes in magnetic properties of certain atomic nuclei. ¹H and ¹³C are the most commonly studied nuclei for their different environments and provide different signals for magnetically non-equivalent nuclei of the same atom present in the same molecule.

In the present chapter, UV-Vis and Infrared spectroscopy have been discussed.

Ultraviolet and Visible Spectroscopy

This absorption spectroscopy uses electromagnetic radiations between 190 nm to 800 nm and is divided into the ultraviolet (UV, 190-400 nm) and visible (VIS, 400-800 nm) regions. Since the absorption of ultraviolet or visible radiation by a molecule leads transition among electronic energy levels of the molecule, it is also often called as electronic spectroscopy. The information provided by this spectroscopy when combined with the information provided by NMR and IR spectral data leads to valuable structural proposals.

Nature of Electronic Transitions

The total energy of a molecule is the sum of its electronic, its vibrational energy and its rotational energy. Energy absorbed in the UV region produces changes in the electronic energy of the molecule. As a molecule absorbs energy, an electron is promoted from an occupied molecular

orbital (usually a non-bonding n or bonding π orbital) to an unoccupied molecular orbital (an antibonding π^* or σ^* orbital) of greater potential energy (figure 3). For most molecules, the lowest-energy occupied molecular orbitals are σ orbitals, which correspond to σ bonds. The π orbitals lie at relatively higher energy levels than σ orbitals and the non-bonding orbitals that hold unshared pairs of electrons lie even at higher energies. The antibonding orbitals (π^* and σ^*) are orbitals of highest energy. The relative potential energies of these orbitals and various possible transitions have been depicted in figure 3.

The saturated aliphatic hydrocarbons (alkanes) exhibit only $\sigma \rightarrow \sigma^*$ transitions but depending on the functional groups the organic molecules may undergo several possible transitions which can be placed in the increasing order of their energies viz. $n \rightarrow \pi^* < n \rightarrow \sigma^* < \pi \rightarrow \pi^* < \sigma \rightarrow \pi^* < \sigma \rightarrow \sigma^*$. Since all these transitions require fixed amount of energy (quantized), an ultraviolet or visible spectrum of a compound would consist of one or more well defined peaks, each corresponding to the transfer of an electron from one electronic level to another. If the differences between electronic energy levels of two electronic states are well defined i.e. if the nuclei of the two atoms of a diatomic molecule are held in fixed position, the peaks accordingly should be sharp. However, vibrations and rotations of nuclei occur constantly and as a result each electronic state in a molecule is associated with a large

Figure 3 : Relative energies of orbitals most commonly involved in electronic spectroscopy of organic molecules

number of vibrational and rotational states. At room temperature, the molecules in the ground state will be in the zero vibrational level ($G_{0,0}$). This is shown schematically in figure 4. The transition of an electron from one energy level to another is thus accompanied by simultaneous change in vibrational and rotational states and causes transitions between various vibrational and rotational levels of lower and higher energy electronic states. Therefore many radiations of closely placed frequencies are absorbed and a broad absorption band is obtained. When a molecule absorbs ultraviolet or visible light of a defined energy, an assumption is made that only one electron is excited from bonding orbital or non-bonding orbital to an anti-bonding orbital and

all other electrons remain unaffected. The excited state thus produced is formed in a very short time i.e. of the order of 10^{-15} seconds. In accordance with Franck-Condon principle, during electronic excitation the atoms of the molecule do not move.

The most probable transition would appear to involve the promotion of one electron from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO), but in many cases several transitions can be observed, giving several absorption bands in the spectrum. We can have a general view of the possible transitions prevailing in organic compounds.

Figure 4 : Energy level diagram showing excitation between different vibrational and rotational levels of two electronic states

Alkanes can only undergo $\sigma \rightarrow \sigma^*$ transitions. These are high-energy transitions and involve very short wavelength ultraviolet light (< 150 nm). These transitions usually fall outside the generally available measurable range of UV-visible spectrophotometers (200-1000 nm). The $\sigma \rightarrow \sigma^*$ transitions of methane and ethane are at 122 and 135 nm, respectively. In alkenes amongst the available $\sigma \rightarrow \sigma^*$ and $\pi \rightarrow \pi^*$ transitions, the $\pi \rightarrow \pi^*$ transitions are of lowest energy and absorb radiations between 170-190 nm.

In saturated aliphatic ketones the lowest energy transition involves the transfer of one electron of the nonbonding electrons of oxygen to the relatively low-lying π^* anti-bonding orbital. This $n \rightarrow \pi^*$ transition is of lowest energy (~ 280 nm) but is of low intensity as it is symmetry forbidden. Two other available transitions are $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$. The most intense band for these compounds is always due to $\pi \rightarrow \pi^*$ transition.

In conjugated dienes the $\pi \rightarrow \pi^*$ orbitals of the two alkene groups combine to form new orbitals – two bonding orbitals named as π_1 and π_2 and two antibonding orbitals named as π_3^* and π_4^* . It is apparent that a new $\pi \rightarrow \pi^*$ transition of low energy is available as a result of conjugation. Conjugated dienes as a result absorb at relatively longer wavelength than do isolated alkenes (see figure 6).

Principles of Absorption Spectroscopy : Beer's and Lambert's Law

The greater the number of molecules that absorb light of a given wavelength, the greater the extent of light absorption and higher the peak intensity in absorption spectrum. If there are only a few molecules that absorb radiation, the total absorption of energy is less and consequently lower intensity peak is observed. This makes the basis of Beer-Lambert Law which states that the fraction of incident radiation absorbed is proportional to the number of absorbing molecules in its path.

When the radiation passes through a solution, the amount of light absorbed or transmitted is an exponential function of the molecular concentration of the solute and also a function of length of the path of radiation through the sample. Therefore,

$$\text{Log } I_0 / I = \epsilon c l$$

Where I_0 = Intensity of the incident light (or the light intensity passing through a reference cell)

I = Intensity of light transmitted through the sample solution

c = concentration of the solute in mol l^{-1}

l = path length of the sample in cm

ϵ = molar absorptivity or the molar extinction coefficient of the substance whose light absorption is under investigation. It is a constant and is a characteristic of a given absorbing species (molecule or ion) in a particular solvent at a particular wavelength. ϵ is numerically equal to the absorbance of a solution of unit molar concentration ($c = 1$) in a cell of unit length ($l = 1$) and its units are $\text{liters.moles}^{-1} \cdot \text{cm}^{-1}$. However, it is customary practice among organic chemists to omit the units.

The ratio I / I_0 is known as transmittance T and the logarithm of the inverse ratio I_0 / I is known as the absorbance A .

Therefore

$$-\text{Log } I / I_0 = -\log T = \epsilon c l$$

and $\text{Log } I_0 / I = A = \epsilon c l$

or $A = \epsilon c l$

For presenting the absorption characteristics of a spectrum, the positions of peaks are reported as λ_{max} (in nm) values and the absorptivity is expressed in parenthesis.

Spectral Measurements

The UV-Vis spectra are usually measured in very dilute solutions and the most important criterion in the choice of solvent is that the solvent must be transparent within the wavelength range being examined. **Table 2** lists some common solvents with their lower wavelength cut off limits. Below these limits, the solvents show excessive absorbance and should not be used to determine UV spectrum of a sample.

Table 2 : Common solvents with their cut-off limits.

S. No.	Solvent	Cut-off wavelength (nm)
1	Acetonitrile	190
2	Water	191
3	Cyclohexane	195
4	Hexane	201
5	Methanol	203
6	95% ethanol	304
7	1,4-dioxane	215
8	Ether	215
9	Dichloromethane	220
10	Chloroform	237
11	Carbon tetrachloride	257
12	Benzene	280

Of the solvents listed in **table 2**, water, 95% ethanol and hexane are the most commonly used solvents. Each is transparent in the region of UV-Vis spectrum. For preparing stock solutions, the sample is accurately weighed and made up to volume in volumetric flask. Aliquats are removed from this solution and appropriate dilutions are made to make solutions of desired concentration. For recording the spectrum 1 cm square quartz cell is commonly used. These require approx. 3 ml of solution. The quartz cell containing solution is placed in the path of light beam and spectrum is recorded by varying the wavelength of incident light.

Solvent Effects

Highly pure, non-polar solvents such as saturated hydrocarbons do not interact with solute molecules either in the ground or excited state and the absorption spectrum of a compound in these solvents is similar to the one in a pure gaseous state. However, polar solvents such as water, alcohols etc. may stabilize or destabilize the molecular orbitals of a molecule either in the ground state or in excited state and the spectrum of a compound in these solvents may significantly vary from the one recorded in a hydrocarbon solvent.

(i) $\pi \rightarrow \pi^*$ Transitions

In case of $\pi \rightarrow \pi^*$ transitions, the excited states are more polar than the ground state and the dipole-dipole interactions with solvent molecules lower the energy of the excited state more than that of the ground state. Therefore a polar solvent decreases the energy of $\pi \rightarrow \pi^*$ transition and absorption maximum appears ~10-20 nm red shifted in going from hexane to ethanol solvent.

(ii) $n \rightarrow \pi^*$ Transitions

In case of $n \rightarrow \pi^*$ transitions, the polar solvents form hydrogen bonds with the ground state of polar molecules more readily than with their excited states. Therefore, in polar solvents the energies of electronic transitions are increased. For example, the figure 5 shows that the absorption maximum of acetone in hexane appears at 279 nm which in water is shifted to 264 nm, with a blue shift of 15 nm.

Figure 5 : UV-spectra of acetone in hexane and in water

Some important terms and definitions

(i) Chromophore: The energy of radiation being absorbed during excitation of electrons from ground state to excited state primarily depends on the nuclei that hold the electrons together in a bond. The group of atoms containing electrons responsible for the absorption is called chromophore. Most of the simple un-conjugated chromophores give rise to high energy transitions of little use. Some of these transitions have been listed in [table 3](#).

Table 3: Absorption maxima of simple un-conjugated chromophores

Chromophore	Transition	ϵ_{\max}	λ_{\max} (nm)
<i>σ – bonded electrons</i>			
(C-C, C-H etc.)	$\sigma \rightarrow \sigma^*$		~ 150
<i>Lone pair electrons</i>			
-O-, -N-, -S-	$n \rightarrow \sigma^*$	100-1000	~ 190
C=O, C=N	$n \rightarrow \pi^*$	15	~300
	$\pi \rightarrow \pi^*$	500	~190
R-C \equiv N	$n \rightarrow \pi^*$	5	~ 170
R-COOH, RCONH ₂ , RCOOR	$n \rightarrow \pi^*$	50	~ 210

π -bonded electrons

C=C	$\pi \rightarrow \pi^*$	14000	~ 190
C \equiv C	$\pi \rightarrow \pi^*$	2000	~ 195
C=O	$\pi \rightarrow \pi^*$	500	~ 180

For example, alkanes contain only single bonds with only possible $\sigma \rightarrow \sigma^*$ type electronic transitions. These transitions absorb radiations shorter than wavelengths that are experimentally accessible in usually available spectrophotometers. In saturated molecules with heteroatom bearing non-bonding pairs of electrons, $n \rightarrow \sigma^*$ transitions become available. These are also high energy transitions. In unsaturated compounds, $\pi \rightarrow \pi^*$ transitions become possible. Alkenes and alkynes absorb ~ 170 nm but the presence of substituents significantly affects their position. The carbonyl compounds and imines can also undergo $n \rightarrow \pi^*$ transitions in addition to $\pi \rightarrow \pi^*$. Amongst these, the most studied transitions are $n \rightarrow \pi^*$ as these absorb at relatively longer wavelength 280-300 nm. These are low intensity (ϵ 10-100) transitions.

(ii) Auxochrome: The substituents that themselves do not absorb ultraviolet radiations but their presence shifts the absorption maximum to longer wavelength are called auxochromes. The substituents like methyl, hydroxyl, alkoxy, halogen, amino group etc. are some examples of auxochromes.

(iii) Bathochromic Shift or Red shift: A shift of an absorption maximum towards longer wavelength or lower energy.

(iv) Hypsochromic Shift or Blue Shift: A shift of an absorption maximum towards shorter wavelength or higher energy.

(v) Hypochromic Effect: An effect that results in decreased absorption intensity.

(vi) Hyperchromic Effect: An effect that results in increased absorption intensity.

Applications of Electronic Spectroscopy in Predicting Absorption Maxima of Organic Molecules

1: Conjugated Dienes, Trienes and Polyenes

The presence of conjugate double bond decreases the energy difference between HOMO and LUMO of resulting diene. The [figure 6](#) shows the change in energy of MO on conjugation. As a result, the radiations of longer wavelength are absorbed. The conjugation not only results in bathochromic shift (longer wavelength) but also increases the intensity of absorption. As the number of conjugated double bonds is increased, the gap between highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) is progressively lowered. Therefore, the increase in size of the conjugated system gradually shifts the absorption maximum (λ_{\max}) to longer wavelength and also increases the absorption. For example, ethylene absorbs at

175 nm ($\epsilon = 1000$) and the conjugation in butadiene gives a strong absorption at longer wavelength at 230 nm and with higher intensity ($\epsilon = >1000$).

Figure 6 : Effect of conjugation on orbitals' energy and respective π - π^* transition.

The presence of alkyl substituents on double bond also produces bathochromic shift and hyperchromic effect. These effects are additive in dienes and up to some extent in trienes. The open chain dienes can achieve *s-cis* or *s-trans* conformations and similarly diene system can be homoannular or heteroannular in cyclic systems. In 1941, Woodward suggested empirical rules for predicting the absorption of open chain and six-membered ring dienes which have been later on extended to large number of dienes and trienes (Table 4).

Table 4: Empirical Rules for Diene and Triene absorptions

Parent open chain or heteroannular diene	214 nm
Homoannular diene	253 nm
Increments for	
(a) each alkyl substituent or ring residue	5 nm
(b) double bond extending conjugation	30 nm
(c) exocyclic double bond	5 nm
(d) lone pair conjugation	
(i) O-C(=O)-R	0 nm
(ii) O-alkyl	6 nm
(iii) S-alkyl	30 nm
(iv) -Cl, -Br	5 nm
(v) NR ₂	60 nm

For example, here the absorption maxima for dienes **1** and **2** have been calculated according to Woodward rules. The comparison of calculated λ_{\max} values with observed λ_{\max} values highlights the importance of these rules.

1

Parent value = 214 nm

Three ring residues (3 x 5) = 15

Exocyclic double bond = 5 nm

Total = 234 nm

Observed value = 235 nm

2

Parent value = 253 nm

Three substituents = 15 nm

Ring residue = 5

Total = 273

Observed value = 275 nm

As the number of double bonds in conjugation increases, the bathochromic (towards longer wavelength) shift in lowest energy absorption maxima is observed. The increase in conjugation gradually shifts the maxima to visible region (> 400 nm) and imparts colour to the sample. **Table 5** shows the λ_{\max} shift in $\text{Me}(\text{CH}=\text{CH})_n\text{Me}$ with increasing number of conjugated double bonds. β -Carotene (**figure 7**) responsible for red color in carrots is a typical example of polyene with 11 conjugated double bonds and exhibits λ_{\max} at 445 nm.

Figure 7: Structure of β -carotene

Table 5: λ_{\max} values for $\text{Me}(\text{CH}=\text{CH})_n\text{Me}$

n	Wavelength (nm)
3	275
4	310
5	342
6	380
7	407

2: Carbonyl Compounds

Carbonyl compounds have two principal UV radiations, the allowed $\pi \rightarrow \pi^*$ transitions and the forbidden $n \rightarrow \pi^*$ transitions. In amides, acids, esters or acid halides, the substituents viz. NR_2 , OH, OR, or $-\text{X}$ on carbonyl group show pronounced hypsochromic effect on the $n \rightarrow \pi^*$ transitions. The hypsochromic effect is due to inductive effect of nitrogen, oxygen or halogen atoms. The heteroatom withdraws electrons from carbonyl carbon and makes carbonyl oxygen lone pair of electrons more stabilized due to its involvement in increasing C=O bond order. As a result, the $n \rightarrow \pi^*$ transition of these compounds is shifted to 200-215 nm range relative to 270 nm in aldehydes and ketones. Conjugation of the carbonyl group with double bond shifts both $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions to longer wavelengths. The effect on $\pi \rightarrow \pi^*$ band is more pronounced. Woodward formulated rules to predict the position of an absorption maximum in an unknown enone. These rules have been summarized in [table 6](#).

Table 6: Empirical Rules for α , β -unsaturated ketones and aldehydes absorption maxima.

Parent acyclic ketone or six-membered		215 nm
Parent α , β -unsaturated pentanone		202 nm
Parent α , β -unsaturated aldehyde		207 nm
<i>Increments for</i>		
(a) a double bond extending conjugation		30 nm
(b) each alkyl group or ring residue	α	10 nm
	β	12 nm
	γ or higher	18 nm
<i>(c) auxochrome</i>		
(i) $-\text{OH}$	α	35 nm
	β	30 nm
	δ	50 nm
(ii) OCOR	α, β, δ	6 nm
(iii) OCH_3	α	35 nm
	β	30 nm
	γ	17 nm
	δ	31 nm
(iv) Cl	α	15 nm
	β	12 nm
(v) Br	α	25 nm
	β	30 nm
(vi) NR_2	β	95 nm
(d) exocyclic double bond		5 nm
(e) Homocyclic diene		30 nm

3. Aromatic Compounds

The simplest aromatic compound is benzene. It shows two primary bands at 184 ($\epsilon = 47,000$) and 202 ($\epsilon = 7400$) nm and a secondary fine structure band at 255 nm ($\epsilon = 230$ in cyclohexane). Substituents on the benzene ring also cause bathochromic and hypsochromic shifts of various peaks. Unlike dienes and unsaturated ketones, the effects of various substituents on the benzene ring are not predictable. However, qualitative understanding of the effects of substituents on the characteristics of UV-Vis spectrum can be considered by classifying the substituents into electron-donating and electron-withdrawing groups.

(i) Effect of Substituents with Unshared Electrons: The non-bonding electrons increase the length of π -system through resonance and shift the primary and secondary absorption bands to longer wavelength. More is the availability of these non-bonding electrons, greater the shift will be. In addition, the presence of non-bonding electrons introduces the possibility of $n \rightarrow \pi^*$ transitions. If non-bonding electron is excited into the extended π^* chromophore, the atom from which it is removed becomes electron-deficient and the π -system of aromatic ring becomes electron rich. This situation causes a separation of charge in the molecule and such excited state is called a charge-transfer or an electron-transfer excited state.

In going from benzene to *t*-butylphenol, the primary absorption band at 203.5 nm shifts to 220 nm and secondary absorption band at 254 nm shifts to 275 nm. Further, the increased availability of *n* electrons in negatively charged *t*-butylphenoxide ion shifts the primary band from 203.5 to 236 nm (a 32.5 nm shift) and secondary band shifts from 254 nm to 290 nm (a 36 nm shift) (Figure 8). Both bands show hyperchromic effect. On the other hand, in the case of anilinium cation, there are no *n* electrons for interaction and absorption properties are quite close to benzene. But in aniline, the primary band is shifted to 232 nm from 204 nm in anilinium cation and the secondary band is shifted to 285 nm from 254 nm (Figure 9).

Figure 8 : UV-spectra of *t*-butyl phenol and *t*-butyl phenoxide in methanol

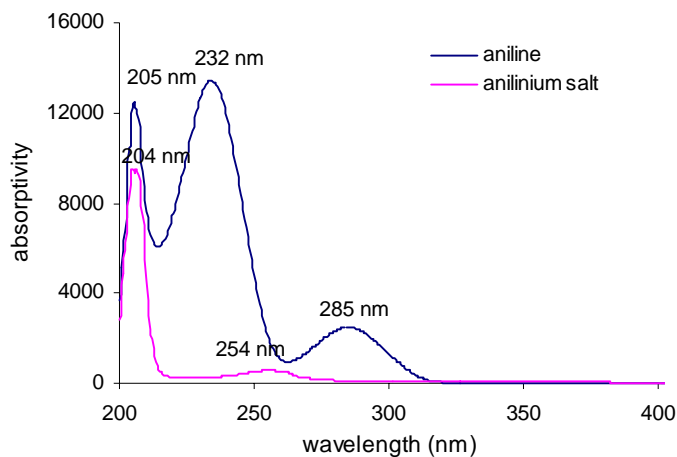

Figure 9 : UV-spectra of aniline and anilinium salt in methanol

(ii) Effect of π Conjugation: Conjugation of the benzene ring also shifts the primary band at 203.5 nm more effectively to longer wavelength and secondary band at 254 nm is shifted to longer wavelength to lesser extent. In some cases, the primary band overtakes the secondary band. For example, benzoic acid shows primary band at 250 nm and secondary band at 273 nm, but cinnamic acid that has longer chromophore exhibits primary band at 273 nm and secondary band remains merged with it. Similarly, in benzaldehyde, the secondary band appears at 282 nm and primary band at 242 nm but in case of cinnamaldehyde, primary band appears at 281 nm and remains merged with secondary band (figure 10). The hyperchromic effect arising due to extended conjugation is also visible.

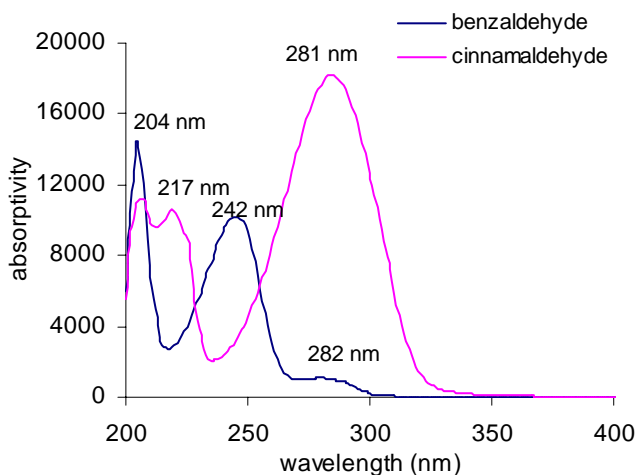

Figure 10 : UV-spectra of benzaldehyde and cinnamaldehyde in methanol

(iii) Effect of Electron-withdrawing and Electron-releasing Groups: Electron-withdrawing substituents viz. NH_3^+ , SO_2NH_2 , CN , COOH , COCH_3 , CHO and NO_2 etc. have no effect on the position of secondary absorption band of benzene ring. But their conjugation effects with π -electrons of the aromatic ring are observed. Electron-donating groups such as $-\text{CH}_3$, $-\text{Cl}$, $-\text{Br}$, $-\text{OH}$, $-\text{OCH}_3$, $-\text{NH}_2$ etc increase both λ_{max} and ϵ_{max} values of the secondary band.

In case of disubstituted benzene derivatives, it is essential to consider the effect of both the substituents.

In para-substituted benzenes, two possibilities exist. If both the groups are electron-donating then the observed spectrum is closer to monosubstituted benzene. The group with stronger effect determines the extent of shifting of primary band. If one group is electron-releasing and other is electron-withdrawing, the magnitude of red shift is greater compared to the effect of single substituent individually. This is attributed to the increased electron drift from electron-donating group to the electron-withdrawing group through π -bond of benzene ring. For example, aniline shows secondary band at 285 nm which due to presence of electron-withdrawing *p*-nitro substituent is shifted to 367 nm with a significant increase in absorptivity (figure 11).

Figure 11 : UV-spectra of aniline and *p*-nitroaniline in methanol

If two groups of a disubstituted benzene derivative are placed ortho- or meta- to each other, the combined effect of two substituents is observed. In case of substituted benzoyl derivatives, an empirical correction of structure with observed position of the primary absorption band has been developed. In the absence of steric hindrance to co-planarity, the calculated values are within ± 5 nm of the observed value.

(iv) Polycyclic Aromatic Compounds: In case of polycyclic aromatic hydrocarbons, due to extended conjugation, both primary and secondary bands are shifted to longer wavelength. These spectra are usually complicated but are characteristic of parent compound. The primary band at 184 nm in benzene shifts to 220 nm in case of naphthalene and 260 nm in case of anthracene.

Similarly, the structured secondary band which appears as broad band around 255 nm in benzene is shifted to 270 nm and 340 nm respectively in case of naphthalene and anthracene molecules.

Commercial Applications of UV and Visible Spectroscopy

The UV-Vis spectroscopy has innumerable applications in the drugs and pharmaceutical industry.

Beer-Lambert law offers a valuable and simple method for quantitative analysis. In practice, a calibration curve is constructed by plotting absorbance vs. molar concentration and the concentration of unknown with 'X' absorbance is determined by finding the concentration corresponding to the measured absorbance on the calibration curve. The UV spectroscopy is used extensively in determining rate constants, equilibrium constants, acid-base dissociation constants etc for chemical reactions. The use of UV spectrometry in evaluation of enzymatic assays has become very common e.g. the activity of enzyme dehydrase is assayed by measuring the formation of ergosterol at 282 nm.

Infrared Absorption Spectroscopy

The two atoms joined together by a chemical bond (may be single, double or triple bond), macroscopically can be composed as two balls joined by a spring. The application of a force like (i) stretching of one or both the balls (atoms) away from each other or closer to each other (ii) bending of one of the atoms either vertically or horizontally and then release of the force results in the vibrations on the two balls (atoms). These vibrations depend on the strength of the spring and also the mode (stretching or bending) in which the force is being applied.

Similarly, at ordinary temperatures, organic molecules are in a constant state of vibrations, each bond having its characteristic stretching and bending frequencies. When infrared light radiations between $4000-400\text{ cm}^{-1}$ (the region most concerned to an organic chemist) are passed through a sample of an organic compound, some of these radiations are absorbed by the sample and are converted into energy of molecular vibrations. The other radiations which do not interact with the sample are transmitted through the sample without being absorbed. The plot of % transmittance against frequency is called the infrared spectrum of the sample or compound.

This study of vibrations of bonds between different atoms and varied multiplicities which depending on the electronegativity, masses of the atom and their geometry vibrate at different but specified frequencies; is called infrared spectroscopy. The presence of such characteristic vibrational bands in an infrared spectrum indicates the presence of these bonds in the sample under investigation.

Hooke's law and Absorption of radiations

The band positions in the IR spectrum are presented in wave numbers ($\bar{\nu}$) whose unit is the reciprocal centimeter (cm^{-1}). $\bar{\nu}$ is proportional to the energy of vibration.

$$\Delta E = h\nu = hc / \lambda = hc \bar{\nu}$$

Therefore, in principle, each absorption of radiation in the infrared region is quantized and should appear as sharp line. However, each vibrational transition within the molecule is

associated with number of rotational energy changes and thus appears as combination of vibrational-rotational bands.

The analogy of a chemical bond with two atoms linked through a spring can be used to rationalize several features of the infrared spectroscopy.

The approximation to vibration frequency of a bond can be made by the application of Hooke's law. In Hooke's law, two atoms and their connecting bond are treated as a simple harmonic oscillator composed of two masses joined by a spring and frequency of vibration is stated as

$$\bar{\nu} \propto \sqrt{\frac{\text{bond strength}}{\text{mass}}}$$

$$\text{then } \bar{\nu} = \frac{1}{2\pi c} \sqrt{\left(\frac{K}{(m_1 m_2) / (m_1 + m_2)}\right)} \quad \text{eq. 1}$$

Where $\bar{\nu}$ = the vibrational frequency (cm^{-1})
 c = velocity of light (cm/s)
 K = force constant of the bond (dyne/cm)
 m_1 and m_2 = masses of the two atoms

The quantity $(m_1 m_2) / (m_1 + m_2)$ is often expressed as μ , the reduced mass of the system.

$$\therefore \bar{\nu} = \frac{1}{2\pi c} \sqrt{\frac{K}{\mu}} \quad \text{eq. 2}$$

Since, according to equation 2

$$\bar{\nu} \propto \sqrt{K}$$

Therefore, the vibrational frequency of a bond would increase with the increase in bond strength. Consequently, we can expect that C=C and C=O stretching will have higher frequencies than C-C and C-O stretching, respectively.

$$\text{also } \bar{\nu} \propto \sqrt{\frac{1}{\mu}}$$

Therefore, the vibrational frequency of a bond would increase with the decrease in reduced mass of the system. It implies that C-H and O-H stretching absorptions should appear at higher frequencies than C-C and C-O stretching frequencies. Similarly, O-H stretching should appear at higher frequency than O-D stretching. Further, in parallel with the general knowledge that the stretching of the spring requires more energy than to bend it, the stretching absorption of a band always appear at higher energy than the bending absorption of the same band.

The Hooke's law can be used to theoretically calculate the approximate stretching frequency of a bond. The value of K is approximately 5×10^5 dyne/cm for single bonds and approximately two and three times this value for the double and triple bonds, respectively.

Let us calculate the approximate frequency of the C-H stretching vibration from the masses of carbon and hydrogen

$$m_C = \text{mass of carbon atom} = 20 \times 10^{-24} \text{ g}$$

$$m_H = \text{mass of hydrogen atom} = 1.6 \times 10^{-24} \text{ g}$$

$$\therefore \bar{\nu} = \frac{7}{2 \times 22} \times \frac{1}{3 \times 10^8} \sqrt{\frac{5 \times 10^5}{(20 \times 10^{-24})(1.6 \times 10^{-24}) / (2.0 + 1.6)10^{-24}}}$$

$$= \sim 3100 \text{ cm}^{-1}$$

Let us consider how the radiations are being absorbed.

We know that at ordinary temperature, molecules are in constant state of vibrations. The change in dipole moment during vibration of the molecule produces a stationary alternating electric field. When the frequency of incident electromagnetic radiations is equal to the alternating electric field produced by changes in the dipole moment, the radiation is absorbed and vibrational levels of the molecule are excited.

Once in the vibrationally excited state, the molecules can lose the extra energy by rotational, collision or translational processes etc. and come back to ground state. Therefore, only those vibrations which result in a rhythmical change in the dipole moment of the molecule absorb infrared radiations and are defined as IR active. The others which do not undergo change in dipole moment of the molecule are IR inactive e.g. the stretching of a symmetrically substituted bond, viz $\text{C}\equiv\text{C}$ in acetylene and symmetrical stretching in carbon dioxide ([figure 13](#)) – a linear molecule, produce no change in the dipole moment of the system and these vibrations cannot interact with infrared light and are IR inactive. In general, the functional groups that have a strong dipole give rise to strong absorption bands in the IR.

Modes of molecular vibrations

Molecules with large number of atoms possess a large number of vibrational frequencies. For a non-linear molecule with n atoms, the number of fundamental vibrational modes is $(3n-6)$; linear molecules have $3n-5$ fundamental vibrational modes. Therefore, water - a non-linear molecule theoretically possesses 3 fundamental vibrations – two stretching and one bending ([figure 12](#)); whereas carbon dioxide - a linear molecule possess 4 fundamental absorption bands involving two stretching and two bending modes ([figure 13](#)).

Amongst these theoretically possible vibrations, a stretching vibration is a rhythmical movement along the bond axis such that interatomic distance is increasing or decreasing. A bending vibration consists of a change in bond angle between bonds with a common atom or the movement of a group of atoms with respect to remaining part of the molecule without movement of the atoms in the group with respect to one another.

Figure 12: *Vibrational modes for water molecule*

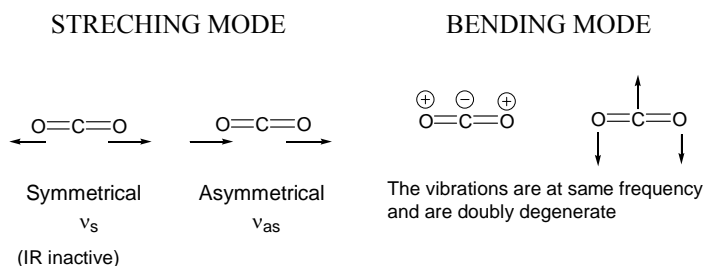

Figure 13: *Vibrational modes for carbon dioxide molecule*

The various stretching and bending modes can be represented by considering an AX₂ group appearing as a portion of molecule, for example, the CH₂ group in a hydrocarbon molecule (figure 14). Any atom joined to two other atoms will undergo comparable vibrations for example NH₂ or NO₂. Each of different vibration modes may give rise to a different absorption band so that CH₂ groups give rise to two C-H stretching bands i.e. ν_{sym} and $\nu_{antisym}$. Some of the vibrations may have the same frequency i.e. they are degenerate and their absorption bands will appear at same position (for CO₂, see figure 13).

BENDING VIBRATIONS

Figure 14: Vibrational modes of a CH₂ group.
[⊕ and ⊖ indicate movement above and below the plane of page]

In addition to the fundamental vibrations, other frequencies can be generated by modulations of the fundamental bands. Overtone bands appear at integral multiples of fundamental vibrations. Therefore, the strong absorptions at say 800 cm⁻¹ and 1750 cm⁻¹ will also give rise to weaker absorptions at 1600 cm⁻¹ and 3500 cm⁻¹, respectively. In the IR spectra of benzaldehyde (figure 30) and acetophenone (figure 31), due to C=O stretching vibration a weak overtone can be seen at 3400 and 3365 cm⁻¹, respectively. Two frequencies may interact to give beats which are combination or difference frequencies. The absorptions at x cm⁻¹ and y cm⁻¹ interact to produce two weaker beat frequencies at x + y cm⁻¹ and x – y cm⁻¹.

Therefore, whereas the factors like degeneracy of bands from several absorptions of the same frequency, lack of change in molecular dipole moment during vibration and fall of frequencies outside the 4000-400 cm⁻¹ region decrease the number of bands whereas the overtone and beats increase the number of bands actually appeared in IR spectrum. Therefore, theoretical numbers of fundamental frequencies are seldom observed.

Other Factors Influencing Vibrational Frequencies

The vibrational frequency of a bond, being part of a molecule, is significantly affected by the electronic and steric factors of the surroundings, in addition to the bond strength and atomic masses discussed above. When two bond oscillators share a common atom, they seldom behave as individual oscillators where the individual oscillation frequencies are widely different. The mechanical coupling interactions between two oscillators are responsible for these changes.

For example, the carbon dioxide molecule, which consists of two C=O bonds with a common carbon atom, has two fundamental stretching vibrations – an asymmetrical and a symmetrical

stretching mode. The symmetrical stretching mode produces no change in dipole moment and is IR inactive. Asymmetric stretching mode is IR active and appears at a higher frequency (2350 cm^{-1}) than observed for a carbonyl group in aliphatic ketones (1715 cm^{-1}).

The carbonyl stretching frequency in RCOCH_3 ($\sim 1720\text{ cm}^{-1}$) is lower than acid chloride RCOCl ($1750\text{-}1820\text{ cm}^{-1}$). This change in frequency of the $\text{C}=\text{O}$ stretching may be arising due to (i) difference in mass between CH_3 and Cl (ii) the inductive or mesomeric influence of Cl on the $\text{C}=\text{O}$ bond (iii) coupling interactions between $\text{C}=\text{O}$ and $\text{C}-\text{Cl}$ bonds (iv) change in bond angles arising due to steric factors etc. It is usually impossible to isolate one effect from the other. However, the appropriate emphasis can be placed on those features that seem to be most responsible in explaining the characteristic appearance and position of group frequencies.

Sample Preparation

For recording an IR spectrum, the sample may be gas, a liquid, a solid or a solution of any of these. The samples should be perfectly free of moisture, since cell materials (NaCl , KBr , CsBr etc.) are usually spoiled by the moisture.

Liquids are studied neat or in solution. In case of neat liquid, a thin film of $< 0.01\text{ mm}$ thickness is obtained by pressing the liquid between two sodium chloride plates and plates are subjected to IR beam. Spectra of solutions are obtained by taking 1-10 % solution of the sample in an appropriate solvent in cells of $0.1\text{-}1\text{ mm}$ thickness. A compensating cell, containing pure solvent is placed in the reference beam of the instrument. The choice of solvent depends on the solubility of the sample and its own minimal absorption in IR region. Carbon tetrachloride, chloroform and carbon disulfide are preferred solvents.

The spectrum of a solid can be obtained either as a mull or as an alkali halide pellet. Mulls are obtained by thoroughly grinding 2-5 mg of a solid sample with a drop of mulling agent usually Nujol (mixture of paraffinic hydrocarbons) or fluorolube (a completely fluorinate polymer). The suspended particles must be less than $2\text{ }\mu\text{m}$ to avoid excessive scattering of radiations. The mull is placed between two sodium chloride plates and plates are subjected to IR beam.

For preparing, an alkali halide pellet, 1-2 mg of dry sample is grinded with $\sim 100\text{ mg}$ of KBr powder. The mixture is then pressed into a transparent pellet with a special die under a pressure of $10,000\text{-}15,000\text{ psi}$. KBr pellet is then mounted on holder and is placed in sample beam of IR spectrophotometer.

Characteristic Group Vibrations of Organic Molecules

An infrared spectrum of an organic compound comprises many bands and assigning each band to a particular mode of vibration is practically impossible but two non-identical molecules generally have different IR spectra. An IR spectrum, therefore, is a fingerprint of the molecule. The region most useful for the purpose of “fingerprinting” of the compound is $650\text{-}1350\text{ cm}^{-1}$. This region comprises a large number of bands due to skeletal vibrations and when the spectrum we are studying coincides exactly with the spectrum of a known compound, it can be safely assumed that the two compounds are identical.

The region above 1350 cm^{-1} often provides easily recognizable bands of various functional groups and thus much valuable structural evidence from relatively few of these bands is

obtained and total interpretation of the complete spectrum is seldom required. In the following sections, the basic information about the vibrational modes in basic functional groups has been discussed.

1. Hydrocarbons C-H and C-C stretching and bending vibrations

(i) Alkanes: In simple hydrocarbons, only two types of atoms - C and H and only two types of bonds – C-C and C-H are present. The C-H stretching vibrations usually occur in the general region between 3300 cm^{-1} (in alkynes) and 2700 cm^{-1} (in aldehydes).

A hydrocarbon containing a methyl group usually shows two distinct bands, one at 2960 cm^{-1} due to asymmetric stretching and the other at 2870 cm^{-1} due to symmetric stretching. The C-H bonds in methylene group undergo number of stretching and bending vibrations as shown in [figure 14](#). The two stretching vibrations – asymmetrical and symmetrical occur at 2925 cm^{-1} and appear in the spectrum within a range of $\pm 10\text{ cm}^{-1}$.

The C-H bending vibrations of the methyl groups in the hydrocarbons normally occur at 1450 and 1375 cm^{-1} . The band at 1375 cm^{-1} is due to methyl on the carbon atom and is quite sensitive to the electronegativity of the substituent present at the methyl group. It shifts from as high as 1475 cm^{-1} in $\text{CH}_3\text{-F}$ to as low as 1150 cm^{-1} in $\text{CH}_3\text{-Br}$. However, this band is extremely useful in detecting the presence of methyl group in a compound because it is sharp and of medium intensity and is rarely overlapped by absorptions due to methylene or methine deformations. The intensity of this band usually increases with the number of methyl groups in the compound. However, the presence of two or more methyl groups on one aliphatic carbon atom (isopropyl or t-butyl groups) results in splitting of this band due to in-phase or out-of phase interactions of the two symmetrical methyl deformations.

In case of methylene group, C-H bending vibrations such as scissoring, twisting, wagging and rocking normally appear at fairly different frequencies. If two or more CH_2 groups are present, the usually strong scissoring and rocking absorption bands appear at 1465 and 720 cm^{-1} , respectively. Whereas weak bands due to twisting and wagging vibrations appear at $1250 \pm 100\text{ cm}^{-1}$. So, the scissoring absorption band of methylene around 1465 cm^{-1} often overlaps with asymmetric bending vibration of methyl at 1450 cm^{-1} .

In cyclic aliphatic hydrocarbons, the C-H stretching frequencies are the same ($2800 - 3000\text{ cm}^{-1}$) as in the case of acyclic compounds, if the ring is unstrained. However, methylene scissoring bands shift slightly to smaller wavenumber (1470 cm^{-1} in hexane and 1448 cm^{-1} in cyclohexane, see [figure 15](#)). In sterically strained cyclic compounds, the C-H stretching normally occurs at slightly higher wavenumber e.g. $3080 - 3040\text{ cm}^{-1}$ in cyclopropane.

The C-C bond vibrations appear as weak bands in $1200-800\text{ cm}^{-1}$ region and are seldom used for structural study. Whereas the C-C bending absorptions occur at $< 500\text{ cm}^{-1}$ and are usually below the range of IR – instrument.

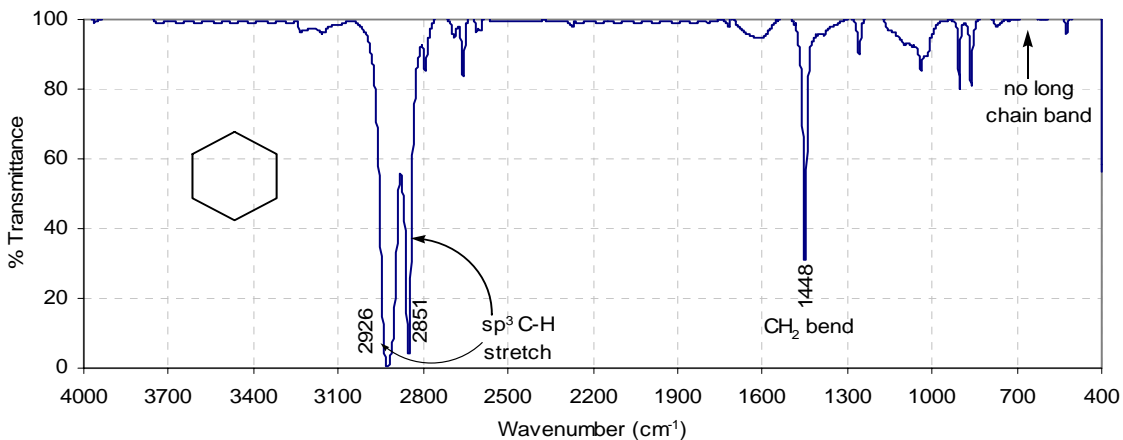

Figure 15 : The infrared spectrum of cyclohexane (neat liquid)

(ii) Alkenes: The carbon-carbon double bond has a higher force constant than a C-C single bond and in a non-conjugated olefin, C=C stretching vibrations appear at higher frequency ($1680\text{-}1620\text{ cm}^{-1}$) than that of the C-C stretching vibrations ($1200\text{-}800\text{ cm}^{-1}$).

In completely symmetrical alkenes, such as ethylene, tetrachloroethylene etc., C=C stretching band is absent, due to lack of change in dipole moment in completely symmetrical molecule. On the other hand, non-symmetrically substituted double bonds exhibit strong absorption bands. The absorption bands are more intense for *cis* isomers than for *trans* isomers; for mono or tri substituted olefins than for di and tetra substituted ones. Also, terminal olefins show stronger C=C double bond stretching vibrations than internal double bonds. Similarly C=C groups conjugated with certain unsaturated group show stronger band than for non-conjugated ones. In case of olefins, conjugated with an aromatic ring, the C=C stretching appears at 1625 cm^{-1} (s) and an additional band at $\sim 1600\text{ cm}^{-1}$ is observed due to aromatic double bond. In compounds containing both olefinic and alkyl C-H bonds, the bands above 3000 cm^{-1} are generally attributed to aromatic or aliphatic C-H stretching, whereas between $3000\text{-}2840\text{ cm}^{-1}$ are generally assigned to the alkyl C-H stretching.

The absorption frequency of a double bond in a cyclic ring is very sensitive to ring size (**figure 16**). The absorption frequency decreases as the internal angle decreases and is lowest in cyclobutene (90° angle). The frequency increases again for cyclopropane.

Figure 16 : C=C vibration frequencies of cycloalkenes

The exocyclic double bonds exhibit an increase in frequency with decrease in ring size (figure 17). The exocyclic double bond on six-membered ring absorbs at 1651 cm^{-1} and it is shifted to 1780 cm^{-1} in case of exocyclic double bond on cyclopropane. The allenes show the highest double bond absorptions at 1940 cm^{-1} .

Figure 17 : Exocyclic C=C double bond frequencies in various ring sizes

(iii) Alkynes : All alkynes both terminal ($\text{R}-\text{C}\equiv\text{CH}$) or non-terminal ($\text{R}-\text{C}\equiv\text{CR}$) contain carbon – carbon triple bond but the non-terminal alkynes also contain a $\equiv\text{C}-\text{H}$ bond. The force constant for a triple bond is greater than that for a double bond. Consequently, whereas a C-C stretching vibrations occur between $1300-800\text{ cm}^{-1}$ and the C=C stretching vibration occur in the region $1700-1500\text{ cm}^{-1}$, the $\text{C}\equiv\text{C}$ vibrations are observed at significantly higher frequencies in the region of 2300 to 2050 cm^{-1} .

The terminal alkynes show weak triple bond stretching vibration at $2140-2050\text{ cm}^{-1}$, whereas the unsymmetrically disubstituted alkynes show a triple bond absorption at $2260-2190\text{ cm}^{-1}$. The acetylene C-H stretching vibrations are normally observed as a sharp characteristic band in the region $3310-3200\text{ cm}^{-1}$ and the acetylenic C-H bending vibrations occur in the region $600-650\text{ cm}^{-1}$.

Therefore the frequency of the absorption of C-H bond is a function of the type of hybridization of the carbon to which hydrogen atom is attached. While moving from sp^3 to sp^2 and sp hybridized carbons, the s-character increases and so is the bond strength (force constant) of C-H bond and the frequency of absorption (Table 7).

Table 7: Important C-H stretching vibrations at a glance

	Vibration	Frequency (cm^{-1})	Intensity
Alkane	Stretch	3000-2850	s
Methyl	bending	1450-1375	m
Methylene	bending	1465	m
Alkene	stretch	3100-3000	m
	bend	1000-650	s
Aromatic	stretch	3150-3000	s
	bend	900-690	s
Alkyne	stretch	3300	s

Aldehyde	2980-2800	w
	2800-2700	w

(iv) Aromatic Hydrocarbons: In the aromatic compounds, the most prominent bands are due to out-of-plane bending of ring C-H bonds in the region of $900\text{-}650\text{ cm}^{-1}$. These bands can be used to assign the ring substitution pattern in mono substituted benzenes and 1,2-, 1,3-, and 1,4-substituted benzene derivatives. Mono substituted benzene derivatives exhibit strong absorption band near 690 cm^{-1} (see IR spectrum of toluene, [figure 18](#)). The absence of this band indicates the absence of mono substituted phenyl rings in the sample. A second strong band appears at $\sim 750\text{ cm}^{-1}$. 1,2-Disubstituted benzenes give one strong absorption band at $\sim 750\text{ cm}^{-1}$. 1,3-Disubstituted rings give three absorption bands at ~ 690 , ~ 780 and $\sim 880\text{ cm}^{-1}$. 1,4-Disubstituted rings give one strong absorption band in the region $800\text{-}850\text{ cm}^{-1}$ (strong absorption band at 831 cm^{-1} is seen in IR spectrum of t-butylphenol, [figure 22](#)). The spectra of aromatic compounds typically exhibit many weak or medium intensity C-H stretching vibrations in the region $3100\text{-}3030\text{ cm}^{-1}$, the region of olefinic compounds.

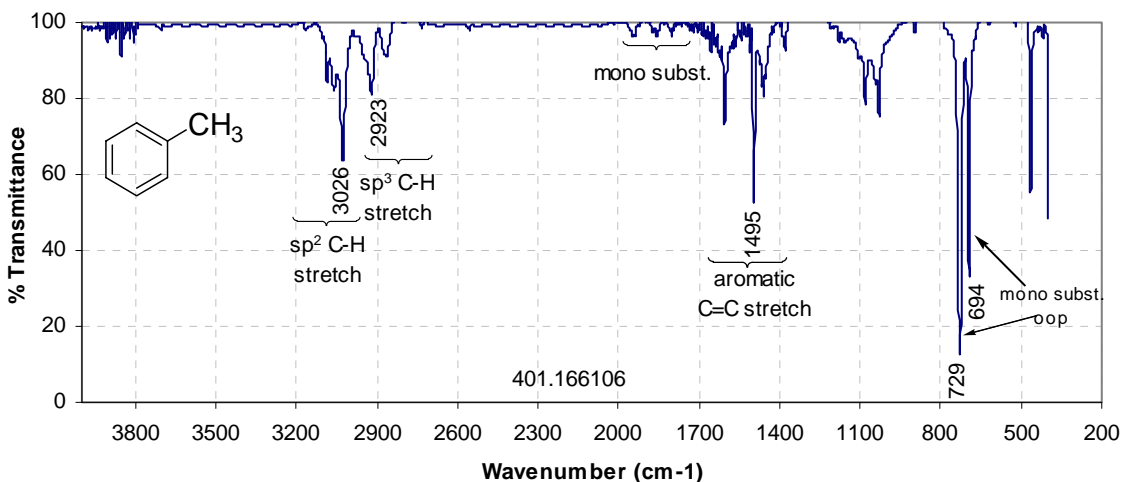

Figure 18 : The infrared spectrum of toluene (neat liquid)

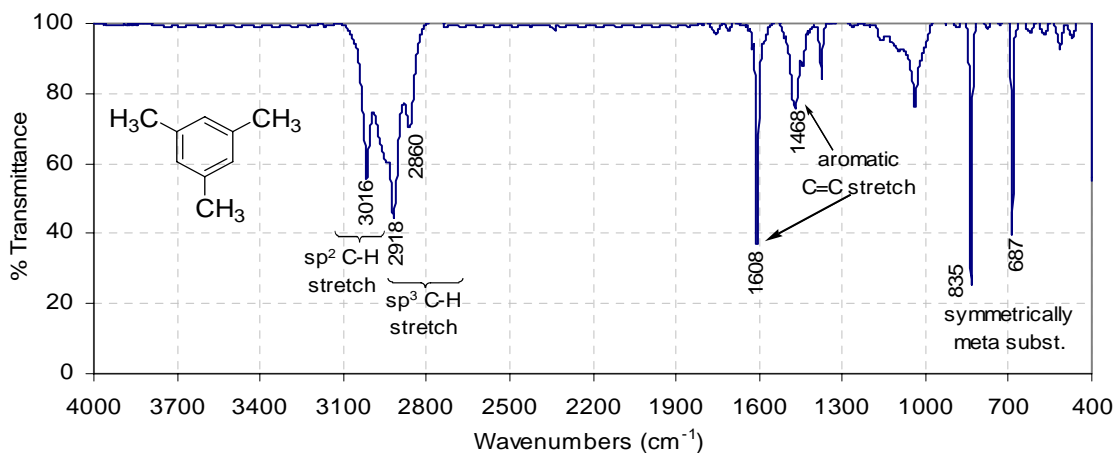

Figure 19 : The infrared spectrum of mesitylene (neat liquid)

The bands considered to be of most help in diagnosing the aromatic character of the compound appear in the region 1650-1400 cm^{-1} . There are normally four bands in this region at about 1600, 1585, 1500 and 1450 cm^{-1} and are due to C=C in-plane vibrations (see spectra in figures 18 and 19). The combination and overtone bands in 2000-1650 cm^{-1} region are also characteristics of aromatic rings. Moreover, they are very weak and are observed only in the case of concentrated solutions of highly symmetric benzene derivatives.

2. Alcohols and Phenols

When a hydrogen atom from an aliphatic hydrocarbon is replaced by an OH group, new bands corresponding to new OH and C-O band absorption appear in the IR spectrum. A medium to strong absorption band from 3700 to 3400 cm^{-1} (see IR spectra of 1-butanol and *t*-butylphenol in figures 21 and 22) is a strong indication that the sample is an alcohol or phenol (The presence of NH or moisture causes similar results). The exact position and shape of this band depends largely on the degree of H-bonding. A strong, sharp peak in the region as higher 3700 cm^{-1} in gaseous or extremely dilute solutions represents unbounded or free OH group(s).

Alcohols and phenols in condensed phases (bulk liquid, KBr discs, concentrated solution etc.) are strongly hydrogen bonded, usually in the form of dynamic polymeric association; dimmers, trimers, tetramers etc. (Figure 20) and cause broadened bands at lower frequencies. The hydrogen bonding involves a lengthening of the original O-H bond. This bond is consequently weakened, force constant is reduced and so the stretching frequency is lowered.

Figure 20 : Polymeric association of ROH

The C-O stretching in phenols / alcohols occurs at a lower frequency range 1250-1000 cm^{-1} . The coupling of C-O absorption with adjacent C-C stretching mode, makes it possible to differentiate between primary ($\sim 1050 \text{ cm}^{-1}$), secondary ($\sim 1100 \text{ cm}^{-1}$) and tertiary ($\sim 1150 \text{ cm}^{-1}$) alcohols and phenols ($\sim 1220 \text{ cm}^{-1}$).

3 Enols and Chelates

Hydrogen bonding in enols and chelates viz. acetyl acetone and methyl salicylate (figure 23), is particularly strong and the observed O-H stretching frequency may be very low (2880 cm^{-1}). Since these bonds are not easily broken on dilution by an inert solvent, free O-H may not be seen at low concentrations. In structures, such as 2,6-di-*t*-butylphenol, in which steric hindrance prevents hydrogen bonding, no bounded O-H band is observed, not even in spectra of neat samples.

acetyl acetone

methyl salicylate

2,6-di-tert.-butylphenol

Figure 23 : H-bonded structures of acetyl acetone and methyl salicylate and sterically hindered 2,6-di-tert.-butylphenol

4. Ethers and Epoxides

In the spectra of aliphatic ethers, the most characteristic absorption is a strong band in the 1150-1000 cm^{-1} region because of asymmetric C-O-C stretching, but a band in this region is also observed in other oxy compounds like alcohols, aldehydes, ketones, acids etc. Therefore, we consider the possibility that a compound is ether or an epoxide only if the unknown oxy compound shows no absorption bands in O-H (3750-3000 cm^{-1}) or carbonyl (1850-1550 cm^{-1}) regions.

The conjugation of ether with carbon-carbon double bond or phenyl ring shifts the C-O-C symmetric stretching to $\sim 1250 \text{ cm}^{-1}$. The resonance increases the bond order from single to partial double bond and so higher the force constant and higher the absorption frequency (figure 24).

Figure 24 : The resonance effects in vinyl ethers and aryl alkyl ether

5 Carbonyl Compounds

The absorption peak for C=O stretching in the region 1870 to 1600 cm^{-1} is perhaps the easiest band to recognize in IR spectrum and is extremely useful in analysis of carbonyl compounds. The changes in C=O stretching frequency in various carbonyl compounds viz. aldehydes, ketones, acids, esters, amides, acid halides, anhydrides etc. can be explained by considering (i) electronic and mass effects of neighboring substituents (ii) resonance effects (both C=C and heteroatom lone pair) (iii) hydrogen bonding (inter and intramolecular) (iv) ring strain etc. It is customary to refer to the absorption frequency of a saturated aliphatic ketone at 1715 cm^{-1} as normal value and changes in the environment of the carbonyl group can either lower or raise the absorption frequency from the “normal” value.

(i) Inductive and Resonance Effects: The replacement of an alkyl group of the saturated aliphatic ketone by a heteroatom (O, N) shifts the C=O stretching frequencies due to inductive and resonance effects. In esters, the oxygen due to inductive effect withdraws the electrons from carbonyl group (figure 25) and increases the C=O bond strength and thus the frequency of absorption. In amides, due to the conjugation of lone pair of electrons on nitrogen atom, the resonance effect increases the C=O bond length and reduces the C=O absorption frequency. Therefore, C=O absorption frequencies due to resonance effects in amides are lowered but due to inductive effect in esters are increased than those observed in ketones.

Figure 25 : Inductive and resonance effects in ester and amide groups

In acid chlorides, the halogen atom strengthens the C=O bond through inductive effect and shifts the C=O stretching frequencies even higher than are found in esters. The acid anhydrides give two bands in C=O stretching frequency region due to symmetric ($\sim 1820 \text{ cm}^{-1}$) and asymmetric ($\sim 1760 \text{ cm}^{-1}$) stretching vibrations (figure 26).

Figure 26 : Inductive effect in acid chloride and C=O stretch in anhydride

(ii) Conjugation Effects: The C=O stretching frequencies for carbon-carbon double bond conjugated systems are generally lower by $25\text{-}45 \text{ cm}^{-1}$ than those of corresponding non-conjugated compounds. The delocalization of π -electrons in the C=O and C=C bonds lead to partial double bond character in C=O and C=C bonds and lowers the force constant (figure 27). Greater is the ability of delocalization of electrons, the more is lowering in C=O stretching frequency. In general *s-cis* conformations absorb at higher frequency than *s-trans* conformations. A similar lowering in C=O stretching frequency occurs when an aryl ring is conjugated with carbonyl compound.

Figure 27 : Resonance effects and *s-cis* and *s-trans* structures in enones

(iii) Ring Size Effects: Six-membered rings with carbonyl group e.g. cyclohexanone absorb at normal value i.e. 1715 cm^{-1} . Decrease in ring size increases the C=O stretching frequency. Smaller rings require the use of more *p*-character to make C-C bonds for the requisite small angles. This gives more *s* character to the C=O sigma bond and thus results in strengthening of C=O double bond.

The comparison of C=O stretching frequencies of various compounds in figure 28 shows that in ketones and esters, $\sim 30 \text{ cm}^{-1}$ increase in frequency occurs on moving to one carbon lower ring.

Figure 28 : C=O stretching frequencies in various compounds

(iv) Hydrogen Bonding Effects: Hydrogen bonding to a C=O group withdraws electrons from oxygen and lowers the C=O double bond character. This results in lowering of C=O absorption frequency. More effective is the hydrogen bonding, higher will be the lowering in C=O absorption frequencies.

Figure 29 : H-bonding effects on C=O stretch

The monomeric carboxylic acids (in very dilute solutions) absorb at $\sim 1760 \text{ cm}^{-1}$. The dimerization of carboxylic acids in their concentrated solutions or in solid state lowers the carboxyl carbonyl frequency to 1710 cm^{-1} . The more effective intramolecular hydrogen bonding in methyl salicylate lowers the C=O stretching frequency to 1680 cm^{-1} than observed at 1700 cm^{-1} in case of methyl *p*-hydroxybenzoate.

a. Aldehydes and Ketones

Aliphatic aldehydes show strong C=O stretching in the region of $1740 - 1725 \text{ cm}^{-1}$. The conjugation of an aldehyde to a C=C or a phenyl group lowers C=O stretching by $\sim 30 \text{ cm}^{-1}$. This effect is seen in benzaldehyde in which aryl group is attached directly to the carbonyl group and shifts C=O stretch to 1701 cm^{-1} (see IR spectrum of benzaldehyde, figure 30). Aldehyde C-H stretching vibrations appear as a pair of weak bands between $2860-2800$ and $2760-2700 \text{ cm}^{-1}$. The higher C-H stretching band ($2860-2800 \text{ cm}^{-1}$) of aldehyde is often buried under aliphatic C-H band. But the lower C-H band at $2760-2700 \text{ cm}^{-1}$ is usually used to distinguish aldehydes from ketones. The C-H bending vibrations appear between $945-780 \text{ cm}^{-1}$.

Figure 30 : The infrared spectrum of benzaldehyde (neat liquid)

The aliphatic acyclic ketones show C=O stretching between 1720 to 1700 cm^{-1} which is shifted to lower frequencies by 20-30 cm^{-1} on conjugation with C=C or phenyl ring. The presence of two conjugated groups as in benzophenone further lowers the C=O stretching frequency to 1665 cm^{-1} (figures 31 and 32).

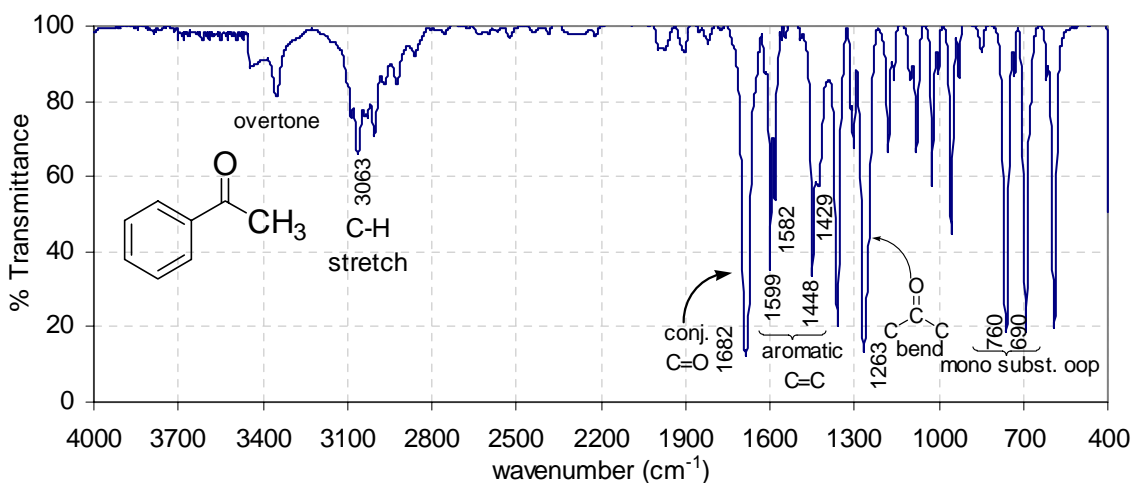

Figure 31 : The infrared spectrum of acetophenone (neat liquid)

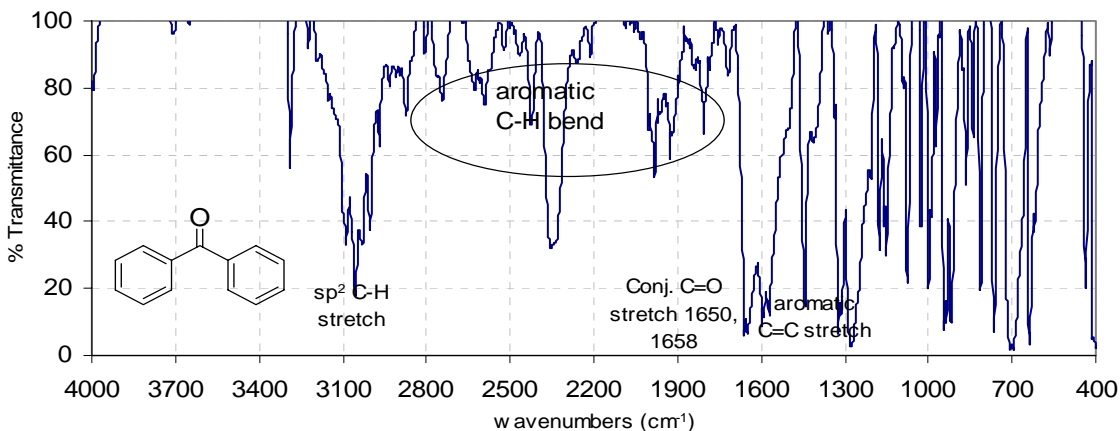

Figure 32 : The infrared spectrum of benzophenone (nujol mull)

In case of cyclic ketones, the coupling between C=O stretching and C(=O)-C single bond causes increase in C=O stretching frequency as the C-C(=O) angle decreases (**figure 28**).

b. Carboxylic Acids, Esters and Carboxylates

In case of carboxylic acids, in solid state or pure liquid state, the intermolecular hydrogen bonding weakens the C=O bond and thus lower the stretching frequency to $\sim 1720 \text{ cm}^{-1}$. The O-H stretch appears as a very broad band between $3400 - 2500 \text{ cm}^{-1}$ (see IR spectrum of benzoic acid, **figure 33**). The appearance of strong C=O stretching along with broad hydroxyl peak centered at $\sim 3000 \text{ cm}^{-1}$ in an IR spectrum certainly shows the presence of carboxylic acid. In addition a medium intensity C=O stretch appears between $1320 - 1260 \text{ cm}^{-1}$. In dilute solutions, the carboxylic acids attain monomeric structures and the inductive effect of oxygen shifts the C=O absorption band to higher values ($1760 - 1730 \text{ cm}^{-1}$) than observed in ketones.

Figure 33 : The infrared spectrum of benzoic acid (nujol mull)

In case of esters, the C=O stretching appears in the range $1750-1730 \text{ cm}^{-1}$ and strong C-O stretching absorption appears in the range $1300 - 1000 \text{ cm}^{-1}$. The esters of α,β -unsaturated or aryl carboxylic acids due to conjugation absorb at lower frequency (**figure 34**).

Figure 34 : Effect of conjugation in cyclic esters

If in an ester, C-O oxygen bears electron-withdrawing group viz vinyl, Ph etc., then the C=O stretching is shifted to higher values ($\sim 1770\text{ cm}^{-1}$) (figures 34 and 35, see IR spectrum of vinyl acetate in figure 36). This increases the electron-withdrawing ability of oxygen causing increase in carbonyl double bond character.

Figure 35 : Resonance effects in vinyl esters

Figure 36 : The infrared spectrum of vinyl acetate (neat liquid)

In cyclic esters (lactones) C=O stretching is shifted to higher frequency with decreasing ring size. Because of ring strain, γ -butyrolactone shows C=O stretching at 1770 cm^{-1} .

In salts of carboxylic acids, expected due to partial carbon – oxygen double bond character the C=O stretching frequency is shifted to lower frequencies at $\sim 1600\text{ cm}^{-1}$.

c. Acid Chlorides and Anhydrides

Both carboxylic acid halides and anhydrides show strong C=O absorptions at characteristically high frequencies $> 1800\text{ cm}^{-1}$ and are easily differentiated from other carbonyl compounds.

The acid anhydrides show two absorption bands in carbonyl region at 1820 cm^{-1} due to symmetric and at 1760 cm^{-1} due to asymmetric stretching vibrations. In case of anhydrides of conjugated carboxylic acids, the frequencies due to these bands are shifted to 1775 and 1720 cm^{-1} . The effect of conjugation is clearly visible in IR spectrum of benzoyl anhydride in [figure 37](#). The strong and broad C-O stretching vibrations appear in the region $1300 - 900\text{ cm}^{-1}$. In case of acid chlorides, the C=O stretching frequencies appear at $1810-1790\text{ cm}^{-1}$ which is attributed to high electronegativity of chlorine.

Figure 37: The infrared spectrum of benzoyl anhydride (nujol mull)

d. Amides

In case of amides strong resonance participation of lone pair of electrons by amide nitrogen weakens the carbonyl bond. Consequently, the C=O stretching frequency in amides appears in the range $1680-1630\text{ cm}^{-1}$ i.e. $20-50\text{ cm}^{-1}$ lower than that of C=O stretching of ketones. The C=O stretching band in IR spectra of amide is called amide I band. In primary and secondary amides, NH deformation band appears in the region $1655 - 1595\text{ cm}^{-1}$ and is called amide II band.

In the solid or pure liquid state, primary amides, which are highly hydrogen bonded, exhibit two N-H stretching bands, one at 3550 cm^{-1} due to N-H asymmetric stretching and other at 3180 cm^{-1} due to N-H symmetric stretching. In dilute solutions, due to lowering in degree of hydrogen bonding, the absorption bands shift to higher frequencies at 3500 and 3400 cm^{-1} , respectively. The secondary amides show only one N-H band at $\sim 3300\text{ cm}^{-1}$. The comparison of double and triple bond stretching vibrations has been given in [table 8](#).

Table 8 : Important double and triple bond Stretching vibrations at a glance

Vibration		Frequency (cm^{-1})	Intensity
<i>Double bonds</i>			
C=C	Alkene	1680-1600	m-w
	Aromatic	1600 and 1475	m-w
C=O	Aldehyde	1740-1720	s

	ketone	1725-1705	s
	COOH	1760-1700	s
	COOR	1750-1730	s
	CONH ₂	1680-1630	s
	Anhydride	1810 and 1760	s
	Acid chloride	1800	s
C=N	Imines	1690-1640	m-s
C=X	Allenes, ketenes, isocyanates	2270-1940	m
N=O	Nitro	1550 and 1350	s
<i>Triple bonds</i>			
C≡C	Alkyne	2250-2100	m-w
C≡N	Nitriles	2260-2240	m

Thus, the vibrational frequencies provide important structural information about a compound and since two same type of bonds in two different compounds would vibrate at different frequencies and so no two compounds can have exactly same infrared spectrum especially in the finger printing region. This makes IR spectroscopy a simple and versatile tool for identification of samples.
