
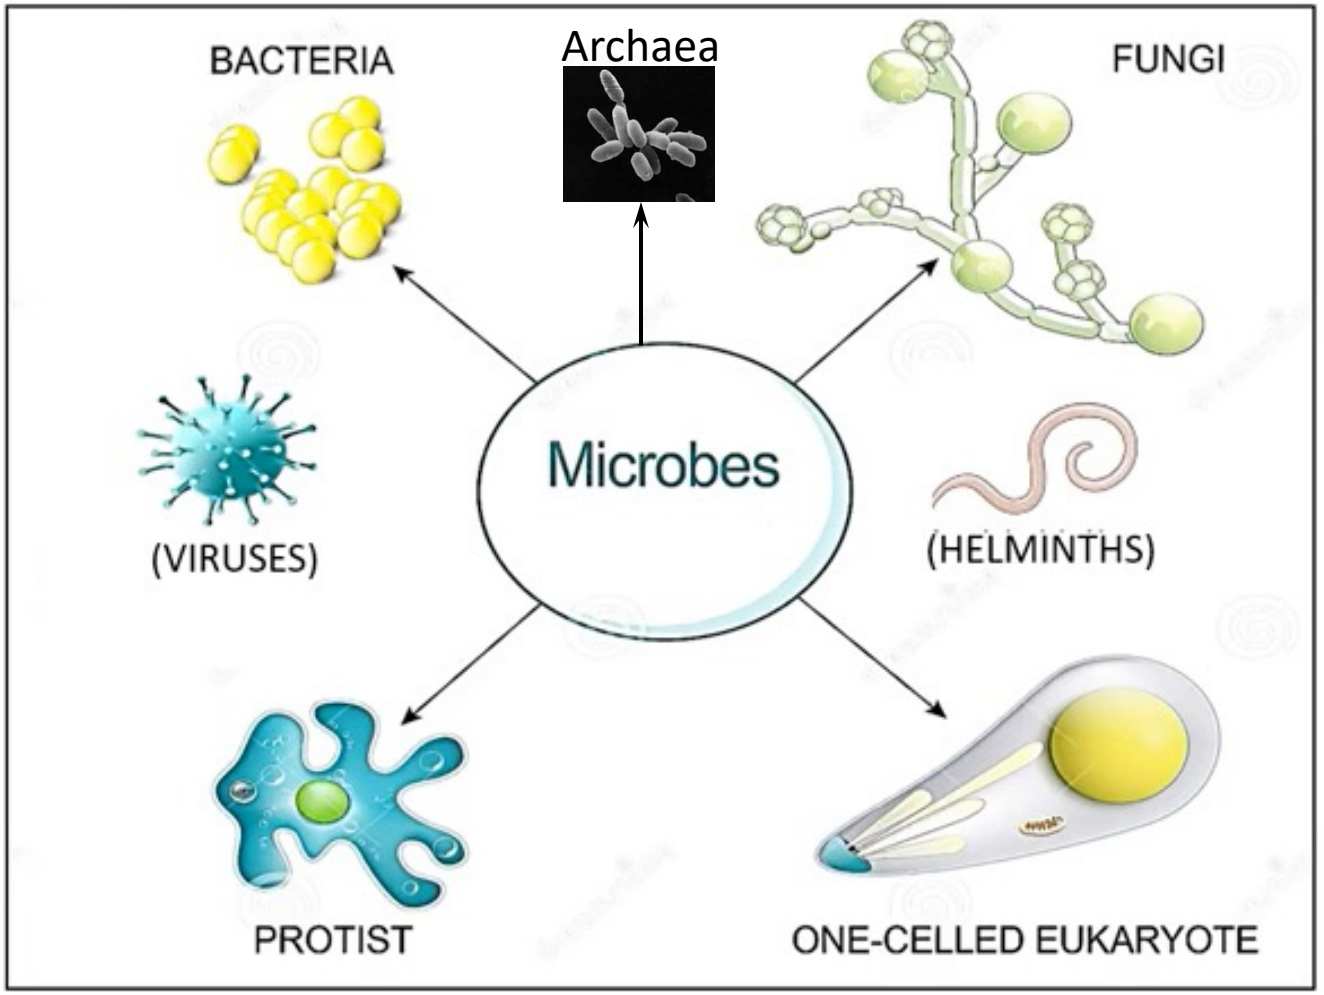
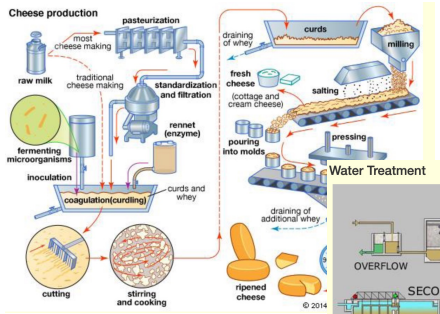
Introduction to Microbiology

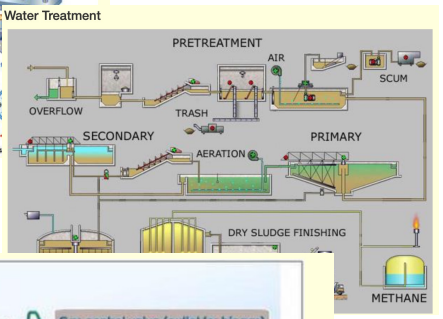
- Microbiology is study of microorganisms, or microbes, a huge diverse group of generally minute (too small to be seen by naked eye) simple life-forms includes; bacteria, archaea, fungi, algae, protozoa, and viruses.

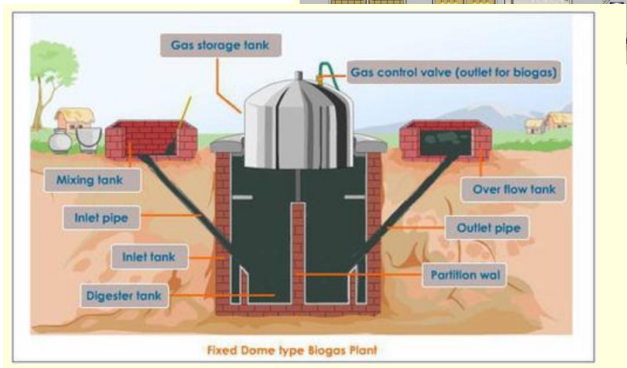


- The field is concerned with the structure, function, and classification of such organisms and with ways of both exploiting and controlling their activities.
- This field study includes basic microbial research, research on infectious diseases, study of prevention and treatment of disease, environmental functions of microorganisms, and industrial use of microorganisms for commercial, agricultural, and medical purposes.

COVID-19 Prevention and Control

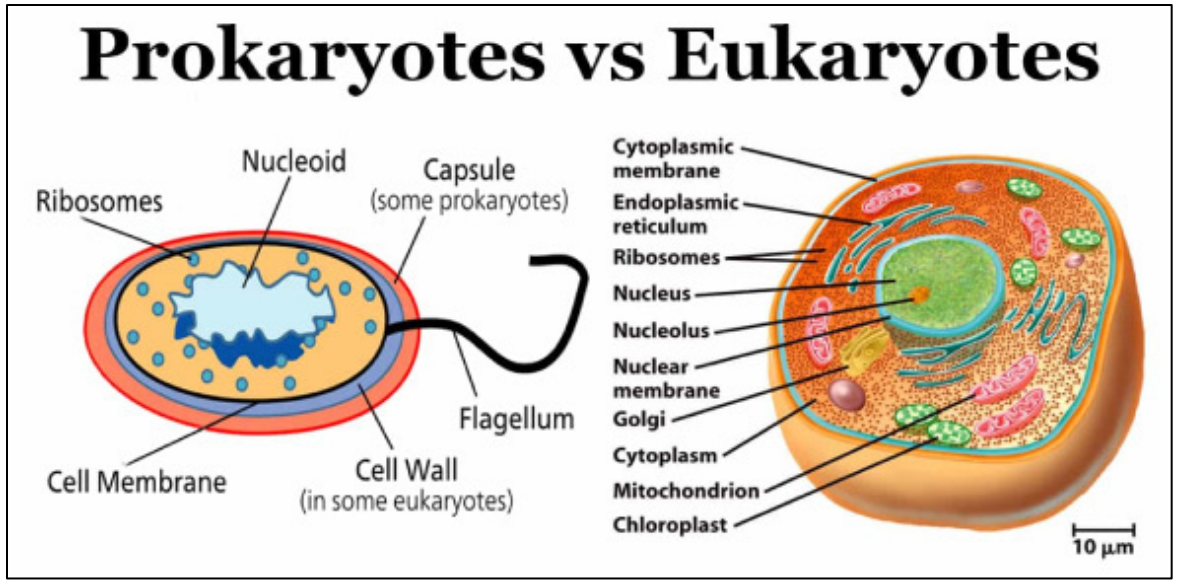




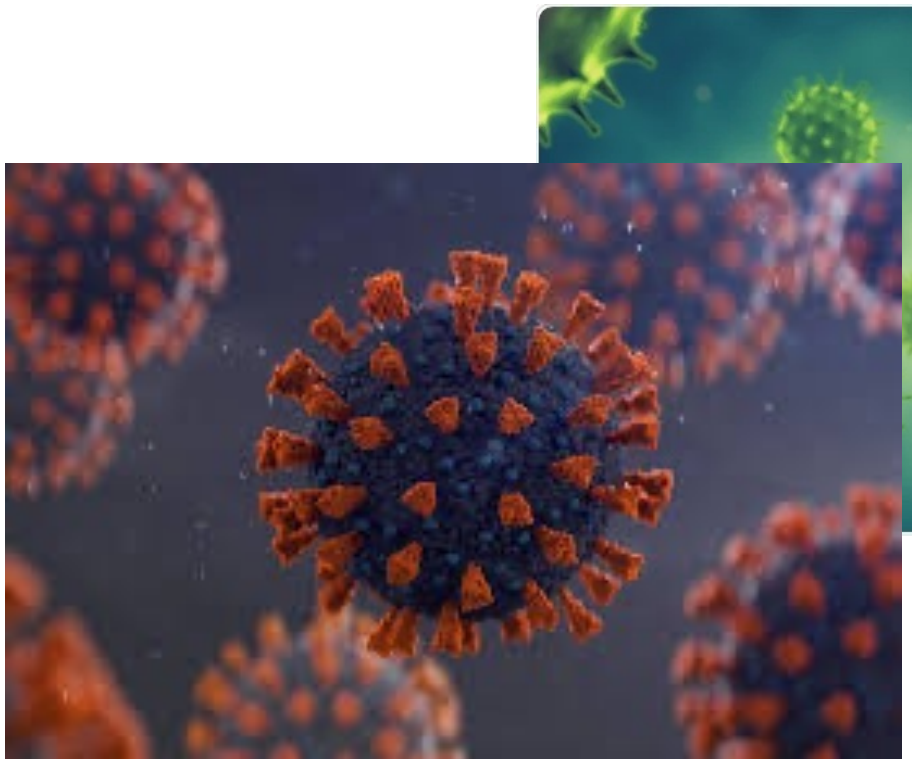


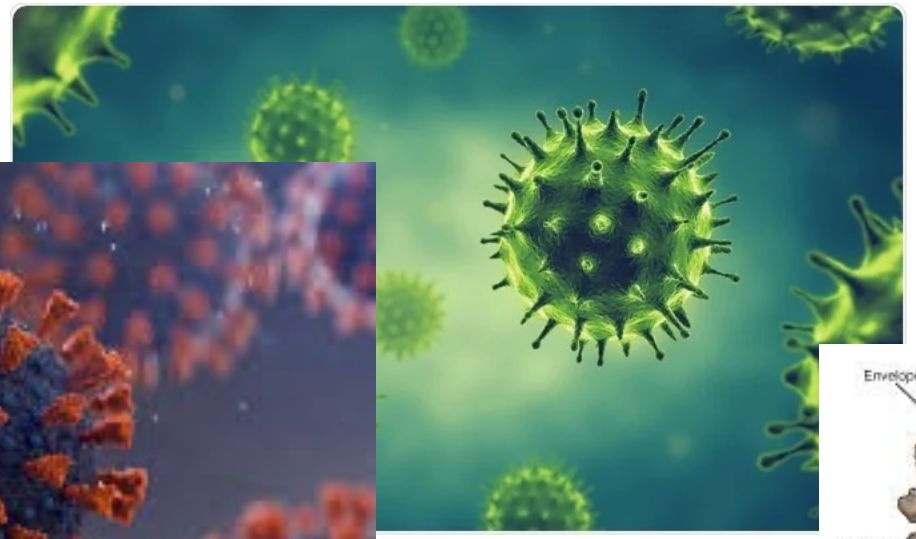
Microorganisms are either unicellular, multicellular or acellular living organisms. And are either **Eukaryotes** or **Prokaryotes**.

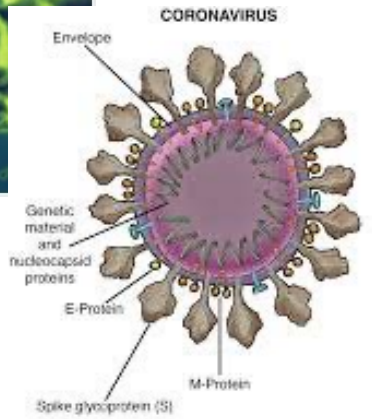
- **-Eukaryotes**; whose cells have a nucleus and organelles (e.g. mitochondria) enclosed within membranes, may also be multicellular and include organisms consisting of many cell type forming different kinds of tissue.
- **-Prokaryotes** is a unicellular that lacks nucleus, mitochondria , or any other organelle. All the intracellular components (proteins, DNA and metabolites) are located together in the cytoplasm enclosed by the cell membrane, rather than in separate cellular compartments.

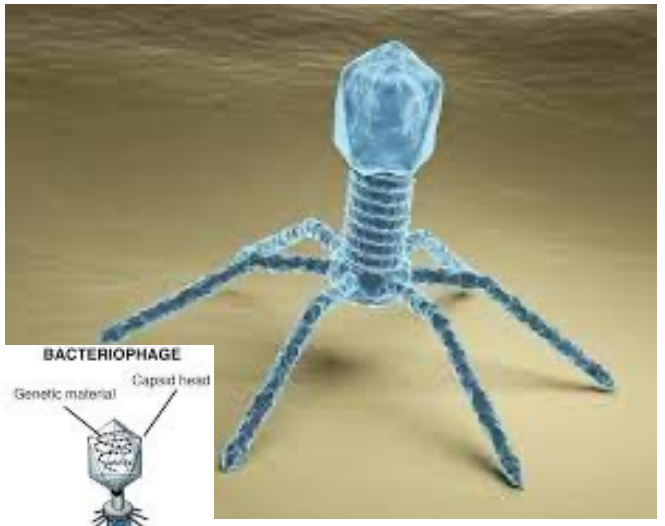


- **Viruses** are acellular microorganisms metabolically inert and therefor replicate only within living cells. They are included in microbiology because of their small size, their close relationship with cells, and their involvement in numerous infectious diseases.

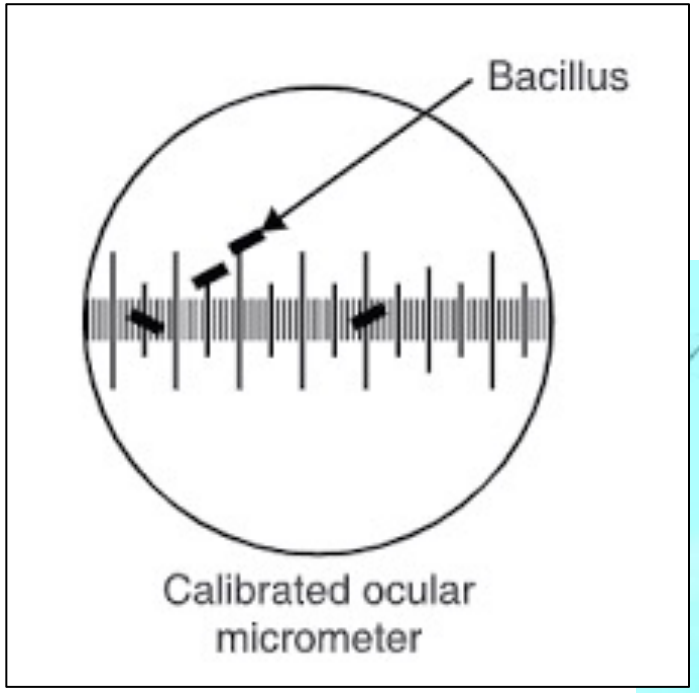


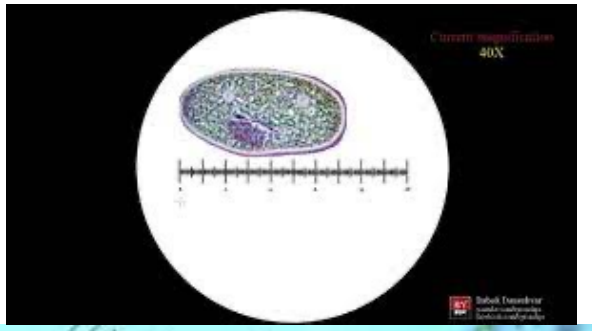


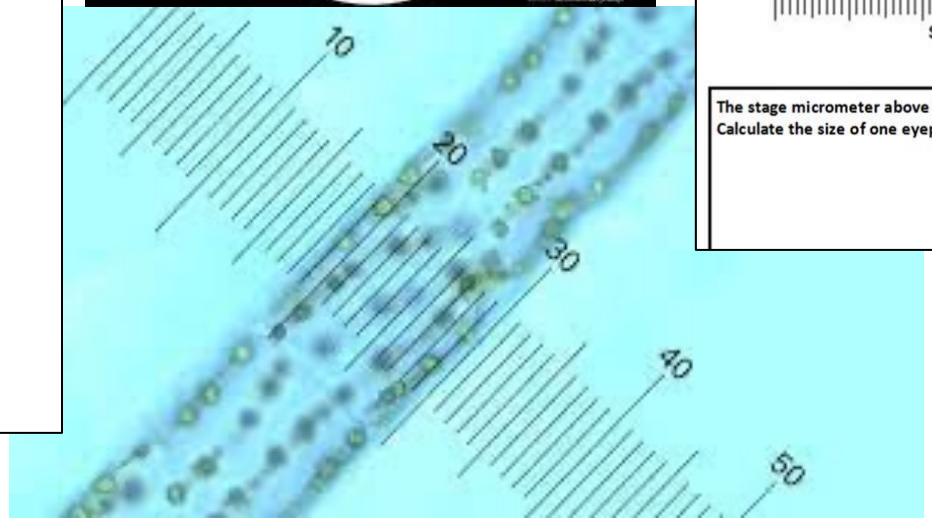


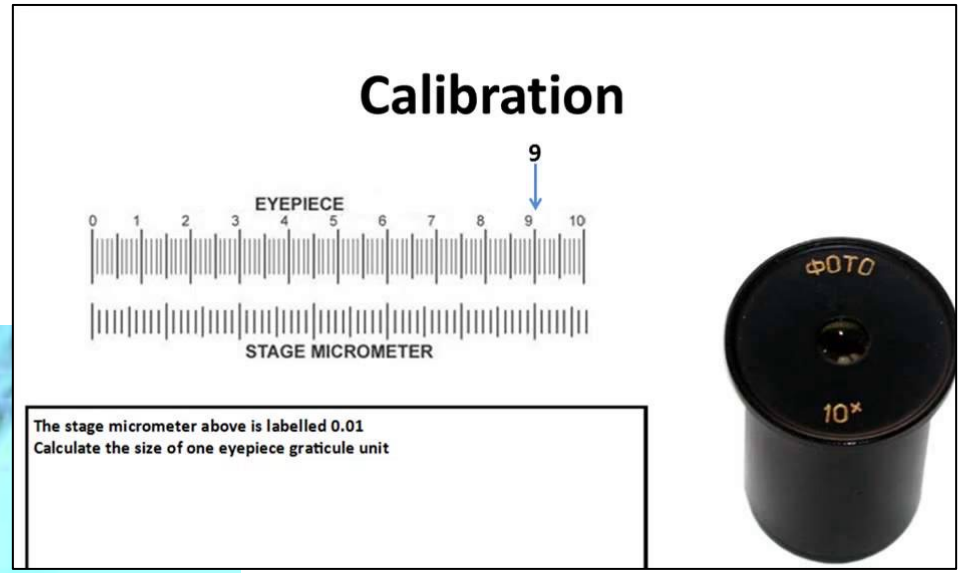


- Most microorganisms are measured in micrometres, with two exceptions.
- The **helminths** are measured in millimetres, and
- the **viruses** are measured in nanometres.

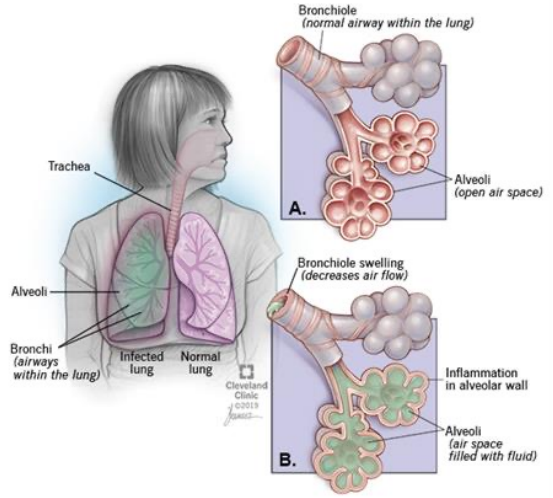






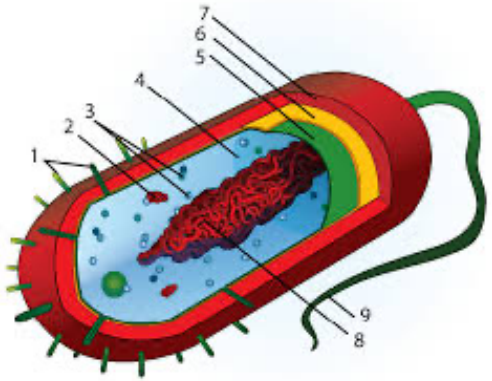


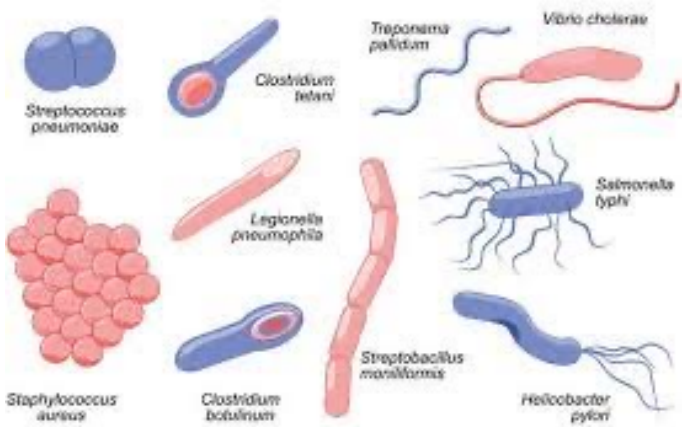
- Microbes have identified as causative agents for over 2,000 infectious diseases. Some infectious diseases are currently emerging and re-emerging. These are on the rise because of rapid travel, the opening up of undeveloped geographic areas, questionable agricultural practices and food handling, drug resistance, and increases in people with chronic medical conditions.



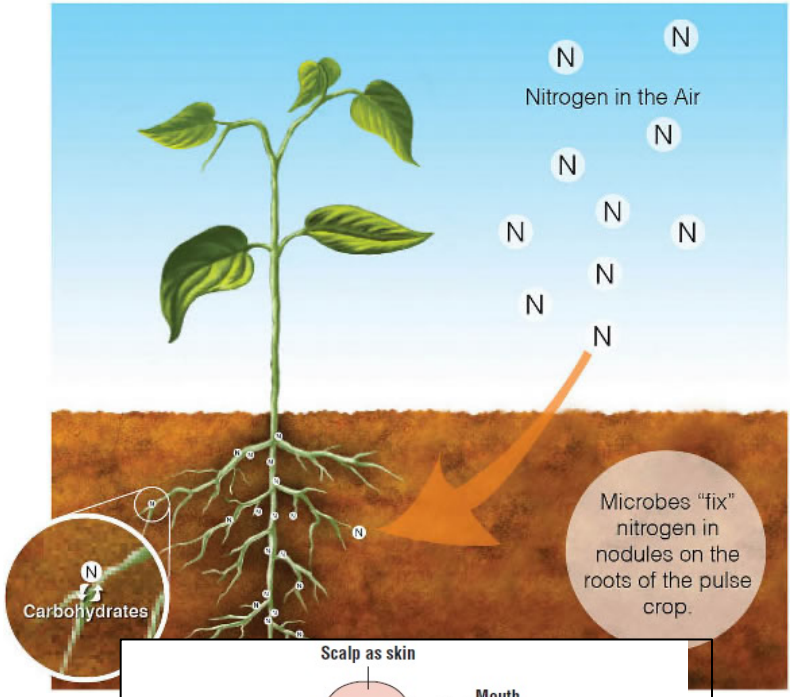
BACTERIA (bacterium)

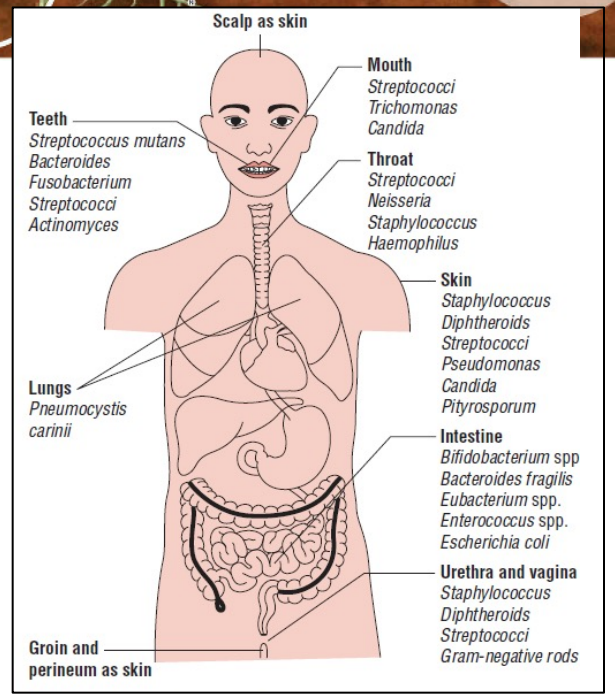
- Bacteria are microscopic single-celled prokaryotic microorganisms that thrive in diverse environments. Typically a few micrometres in length, bacteria have a number of shapes , ranging from spheres to rods and spirals. Bacteria inhabit soil, water, acidic hot springs, radioactive waste, and the deep portions of Earth's crust. Bacteria also live in symbiotic and parasitic relationships with plants and animals.
- There are typically 40 million bacterial cells in a gram of soil and a million bacterial cells in a millilitre of fresh water.





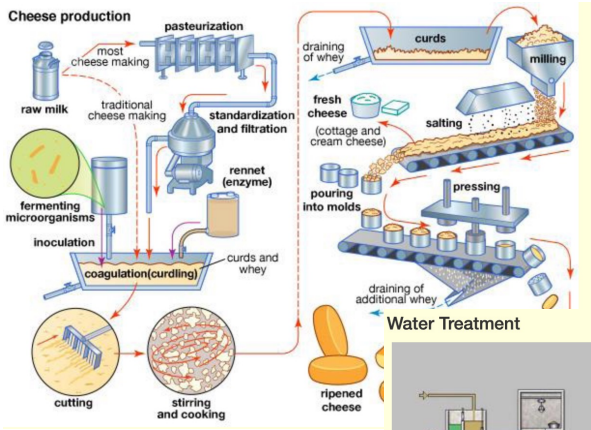
- Bacteria are vital in recycling nutrients, with many of the stages in nutrient cycles such as the fixation of nitrogen from the atmosphere and putrefaction.
- There are approximately ten times as many bacterial cells in the human flora as there are human cells in the body, with the largest number of the human flora being in the gut flora, and a large number on the skin. The vast majority of the bacteria in the body are rendered harmless by the protective effects of the immune system, and some are beneficial.

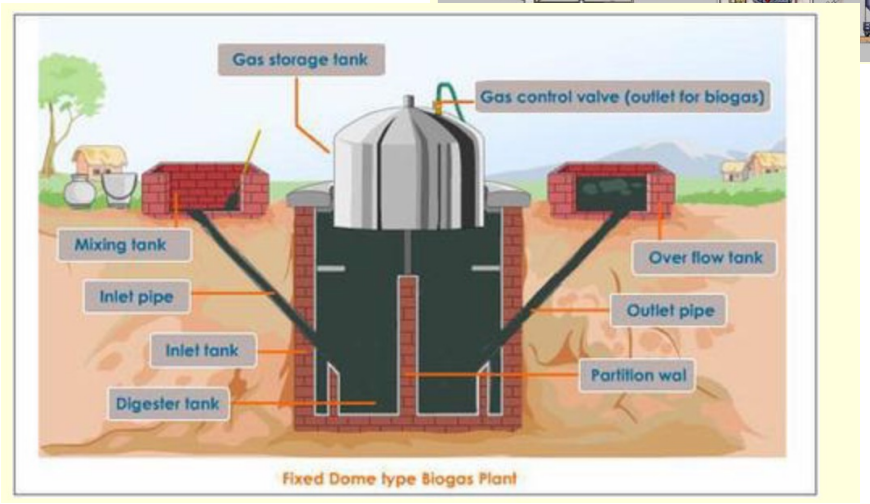




- However, several species of bacteria are pathogenic and cause infectious diseases, like
- **cholera** (*Vibrio cholera*e),
- **syphilis**(*Treponema pallidum*),
- **anthrax**(*Bacillus anthra*cis)
- **leprosy** (*Mycobacterium leprae*)
- and **plague**(*Yersinia pestis*) ,
- The most common fatal bacterial diseases are respiratory infections, with tuberculosis (*Mycobacterium tuberculosis*) alone killing about 2 million people a year ,mostly in Africa.

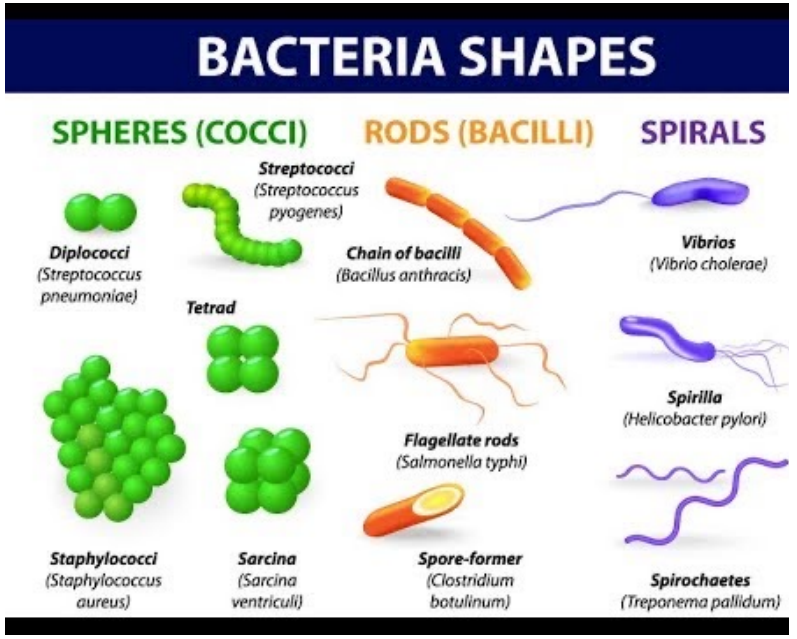
- In developed countries, antibiotic care used to treat bacterial infections. However wrong use of antibiotic might leads to antibiotic resistance, a growing problem. In industry, bacteria are important in sewage treatment and the breakdown of oil spills, the production of cheese and yogurt through fermentation, and the recovery of gold, copper and other metals in the mining sector, as well as in biotechnology, and the manufacture of antibiotics and other chemicals.



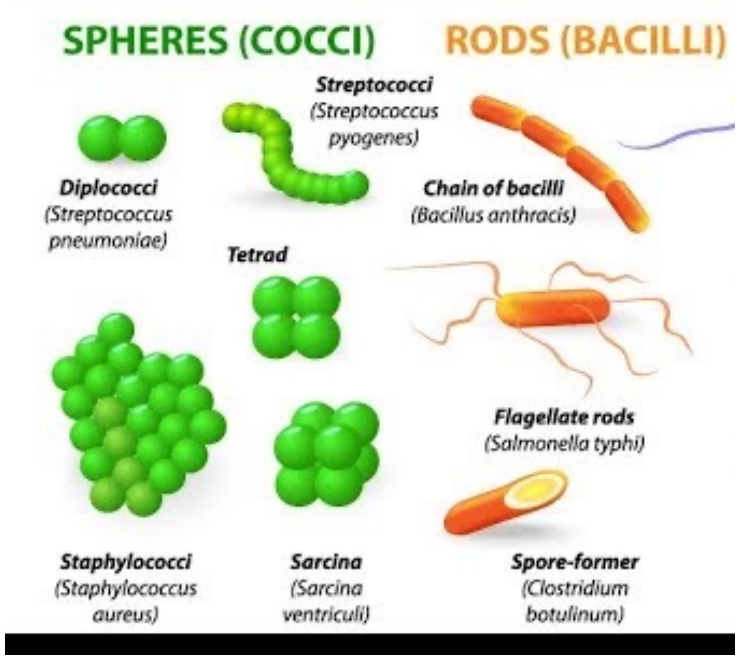


Bacterial Morphology

- Bacteria display a wide diversity of shapes and sizes. Bacterial cells are about tenth-one the size of eukaryotic cells and are typically 0.5– 5.0 micrometres in length.
- Bacteria can be classified by direct examination with the light microscope according to their morphology and arrangement.
- Most bacterial shaped (Fig.1) are either:
- 1-Spherical (coccus), (e.g. *Staphylococcus aureus*).
- 2-Rod shaped with round-ended cylinders (bacillus)
- 3- Slightly curved rods or comma-shaped (vibrio) (e.g. *Bacillus anthracis*).
- 4- Spiral-shaped, called **spirilla** (e.g. *Helicobacter pylori*)
- *5*-Tightly coiled, called **spirochetes** (e.g. *Treponema pallidum*) .

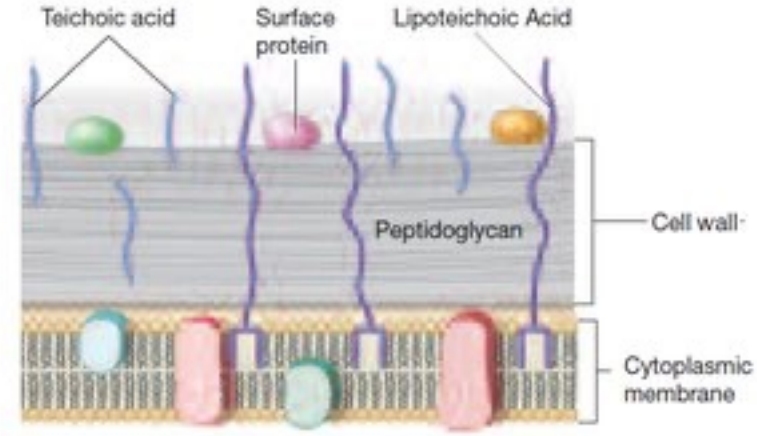


- This wide variety of shapes is determined by the **bacterial cell wall** and **cytoskeleton,** and is important because it can influence the ability of bacteria to acquire nutrients, attach to surfaces, swim through liquids and escape predators.
- Arrangements of cells are based on the number of planes in which a given cell divides. Cocci can divide in many planes to form pairs (diplococci) (*Streptococcus pneumonia*) , chains (streptococci), packets or clusters (micrococci or staphylococci). Bacilli divide only in the transverse plan. If they remain attached, they form pairs, chains, or palisades arrangements.

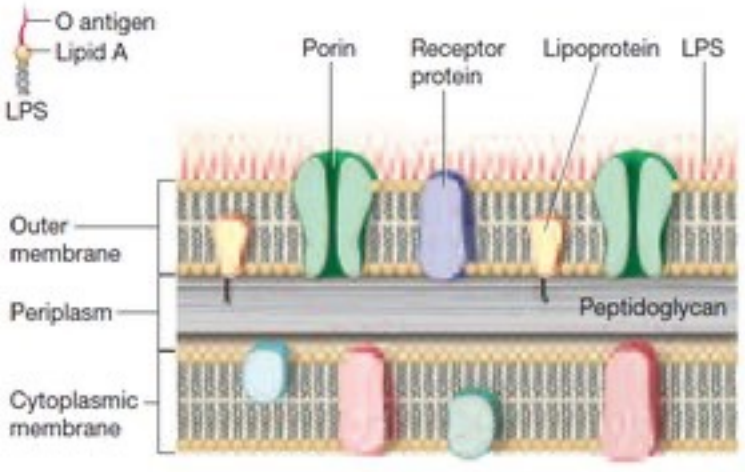


Bacterial Cell Wall

- Bacterial cell wall provides structural safety to the cell. In prokaryotes, the primary function of the cell wall is to protect the cell from internal pressure caused by the much higher concentrations of proteins and other molecules inside the cell compared to its external environment.
- The bacterial cell wall differs from that of all other organisms by the presence of peptidoglycan which is located immediately outside of the cytoplasmic membrane.

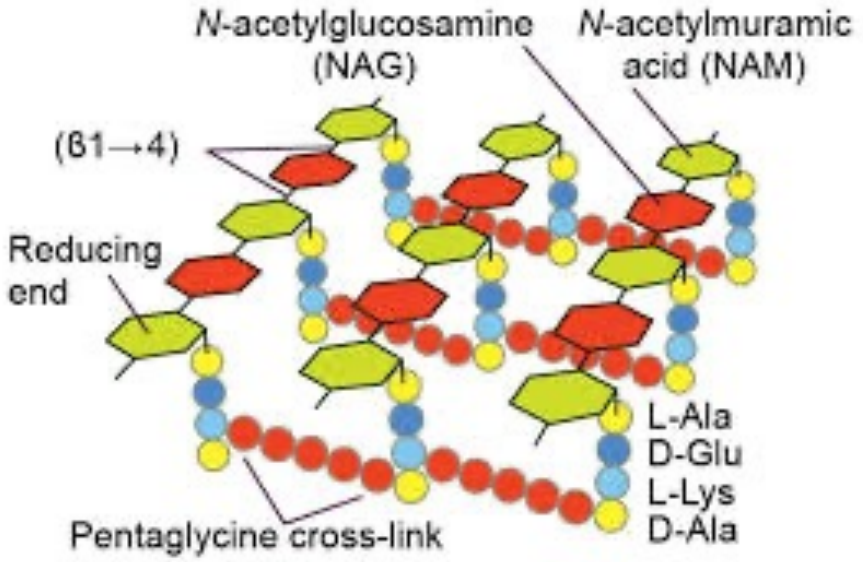


Cell Wall of Gram Positive Organism

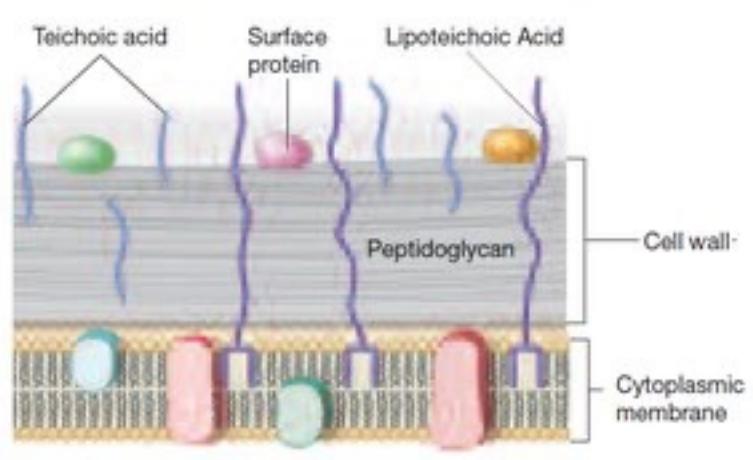


Cell Wall of Gram Negative Organism

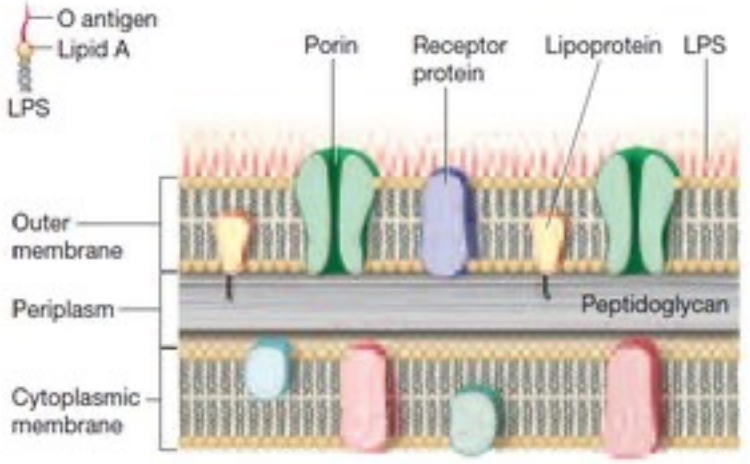
- Peptidoglycan is made up of a polysaccharide backbone consisting of alternating N-Acetylmuramic acid (NAM) and N-acetylglucosamine (NAG) residues in equal amounts. Peptidoglycan is responsible for the rigidity of the bacterial cell wall and for the determination of cell shape. It is relatively porous and is not considered to be a permeability barrier for small substrates.



- While most of bacterial cell walls contain peptidoglycan, not all cell walls have the same overall structures. There are two main types of bacterial cell walls, those of gram-positive bacteria and those of gram-negative bacteria, which are differentiated by their Gram staining characteristics.



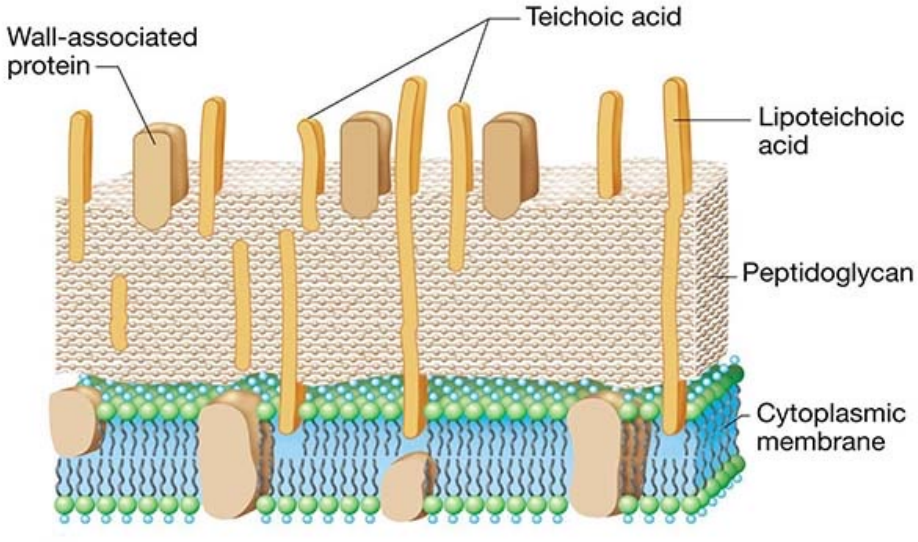
Cell Wall of Gram Positive Organism



Cell Wall of Gram Negative Organism

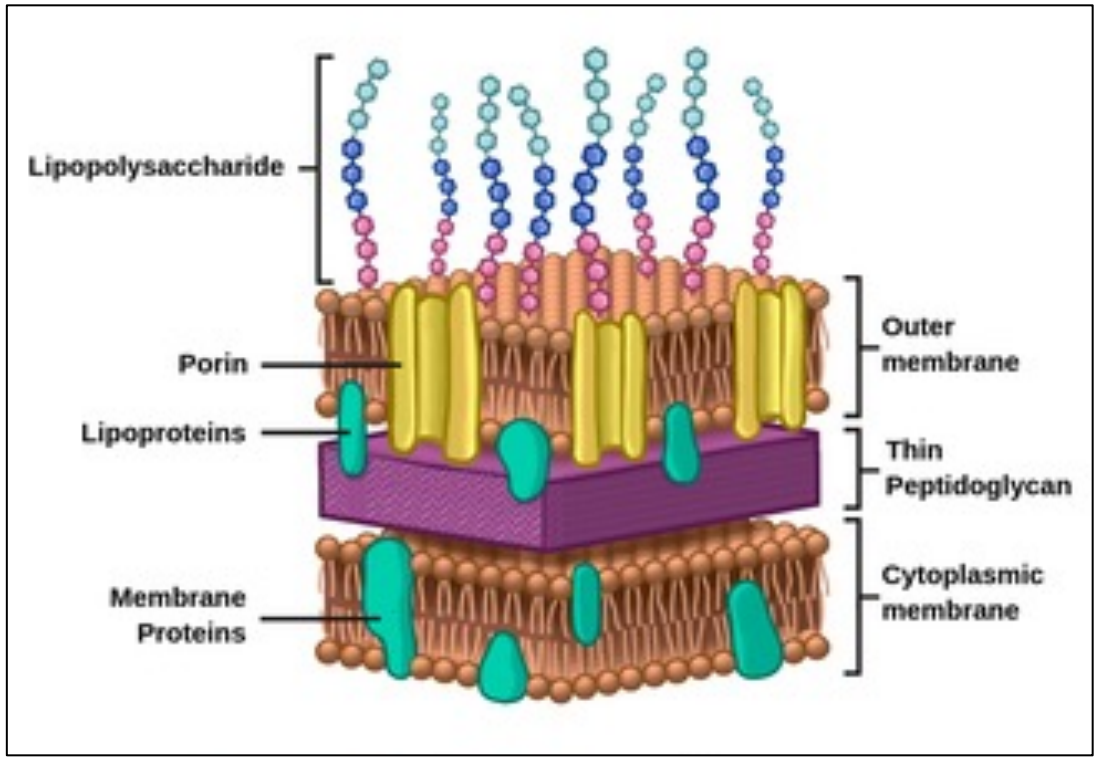
The gram-positive cell wall

- Gram-positive cell wall (Its bacteria stained as purple colour by Gram stain) has a thick peptidoglycan layer and it constitutes almost 95% of the cell wall in some gram-positive bacteria. It also contains teichoic acid and lipoteichoic acid directly attached to the peptidoglycan.
- There are two main types of teichoic acid: ribitol teichoic acids and glycerol teichoic acids. The latter one is more widespread. These acids are polymers of ribitol phosphate and glycerol phosphate, respectively, and only located on the surface of many gram-positive bacteria.

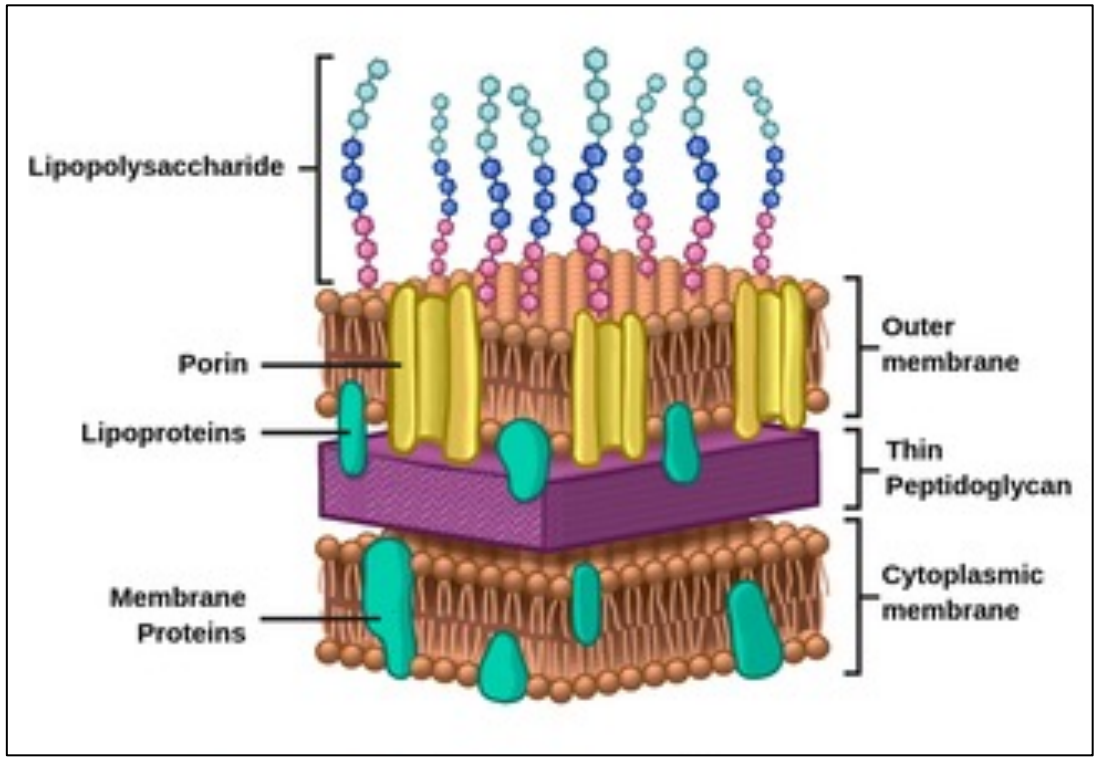


The Gram-negative cell wall

- Gram-negative cell walls are unlike the gram-positive cell walls, they composed of an outer membrane (OM) and a thinner shell of peptidoglycan layer adjacent to the cytoplasmic membrane. Gram-negative bacteria are stained as pink colour by gram stain. The outer membrane contains a unique component, lipopolysaccharide (LPS) in addition to proteins and phospholipids.

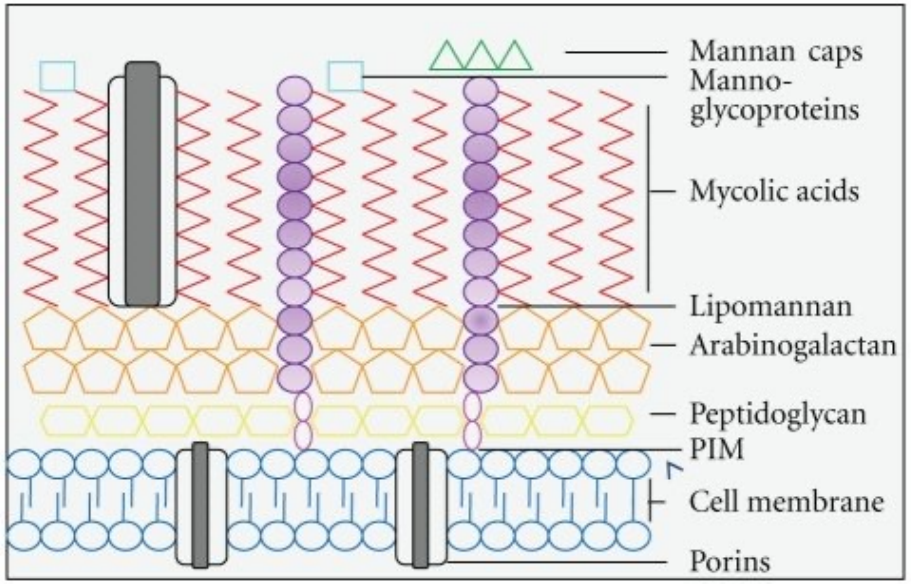


- The chemical structure of lipopolysaccharides is often unique to specific bacterial sub-species and is responsible for many of antigenic properties of these strains.
- Lipopolysaccharides, also called (endotoxins), are composed of polysaccharides and lipid A which are responsible for much of the toxicity of Gram-negative bacteria.



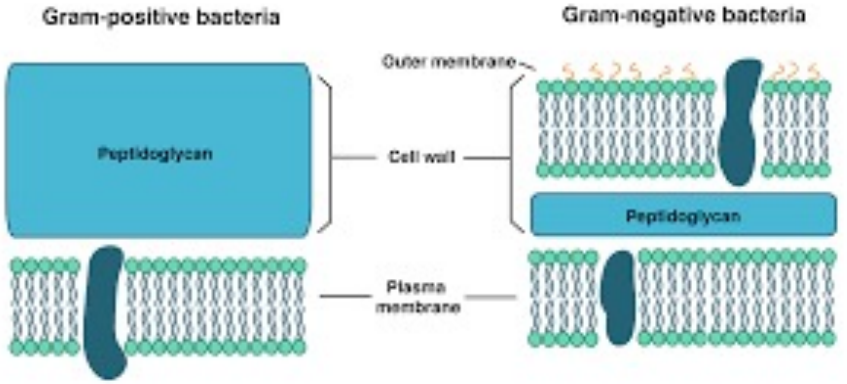
Non typical cell wall

- **Mycobacterium and Nocardia** contain peptidoglycan and stain gram positive, but their cell wall is composed of unique types of lipids.
- **Mycoplasmas** are bacteria that naturally lack a cell wall. Its cell membrane contains sterols that make it resistant to lysis.



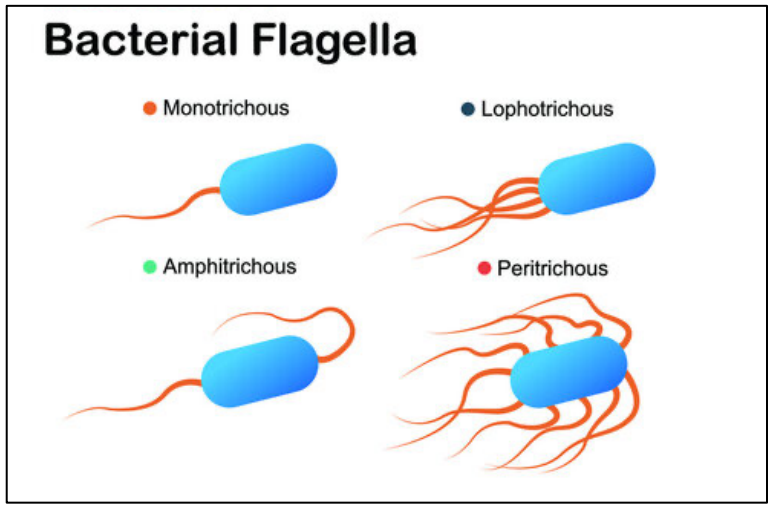
Plasma membrane

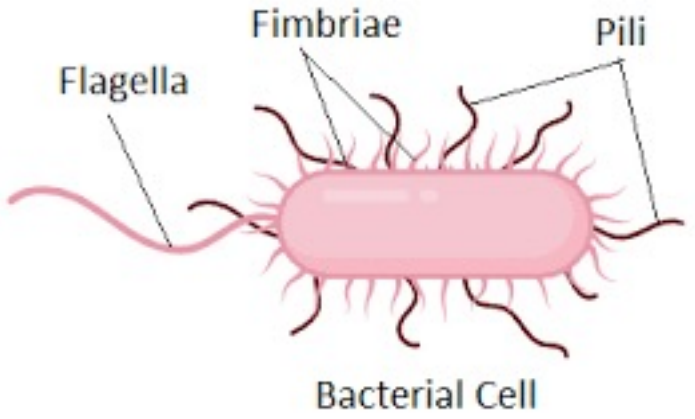
- The plasma membrane or bacterial cytoplasmic membrane is composed of a phospholipid bilayer.
- The General functions of a cell membrane are **acting as a permeability barrier** for most molecules and serving as the location for the **transport of molecules** into the cell and **energy conservation**.
- The region between the cytoplasm membrane and the outer membrane is called a periplasm. There are channels called porins present in the outer membrane that allow for passive transport of many ions, sugars and amino acids across the outer membrane to the periplasm and than be transported into the cell by The plasma membrane.



Cell Extensions and Surface Structures

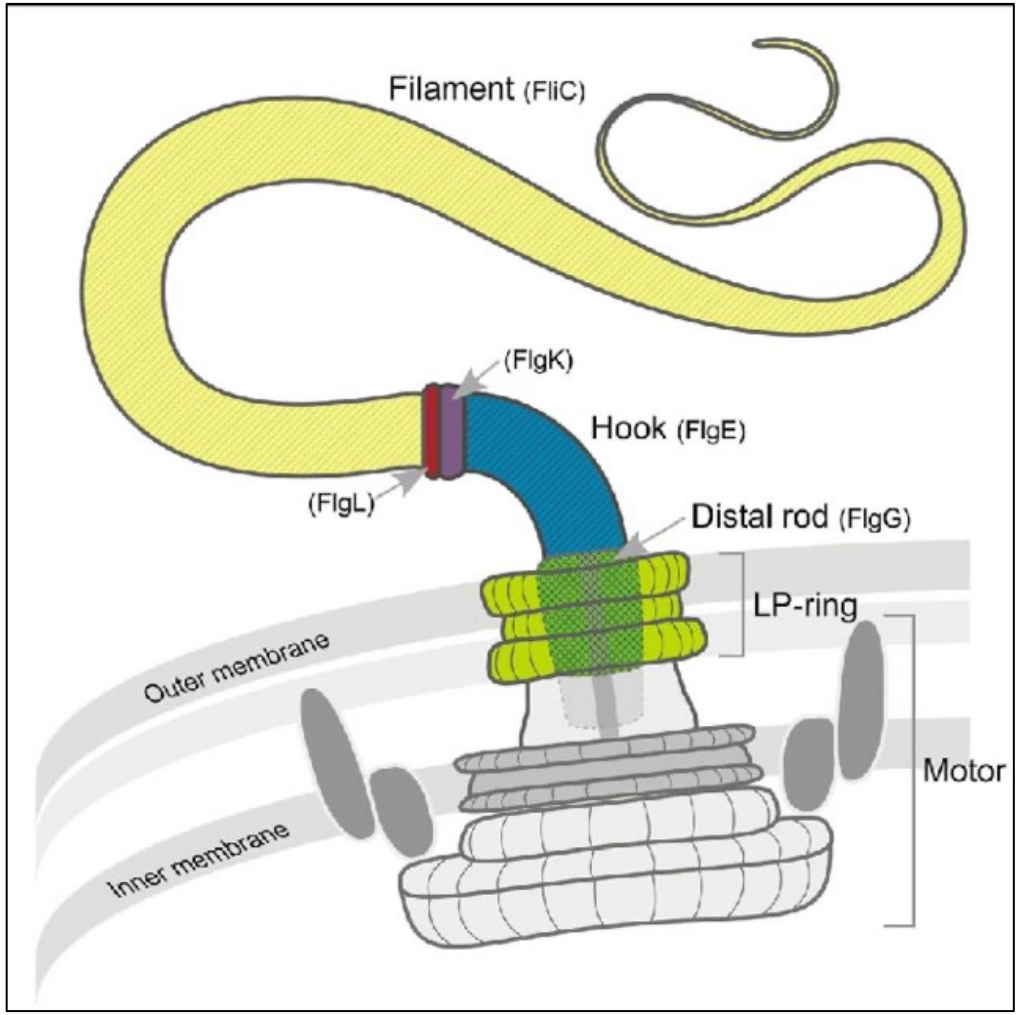
- Bacteria often have accessory **appendages** sprouting from their surfaces. Appendages can be divided into two major groups:
- those that provide motility (flagella and axial filaments) and
- those that provide attachments or channels (fimbriae and pili).





Flagella—Bacterial Propellers

- The prokaryotic **flagellum** is provide the power of motility. This allows a cell to swim freely through an aqueous habitat.
- The bacterial flagellum when viewed under high magnification displays three distinct parts: the filament, the hook (sheath), and the basal body.



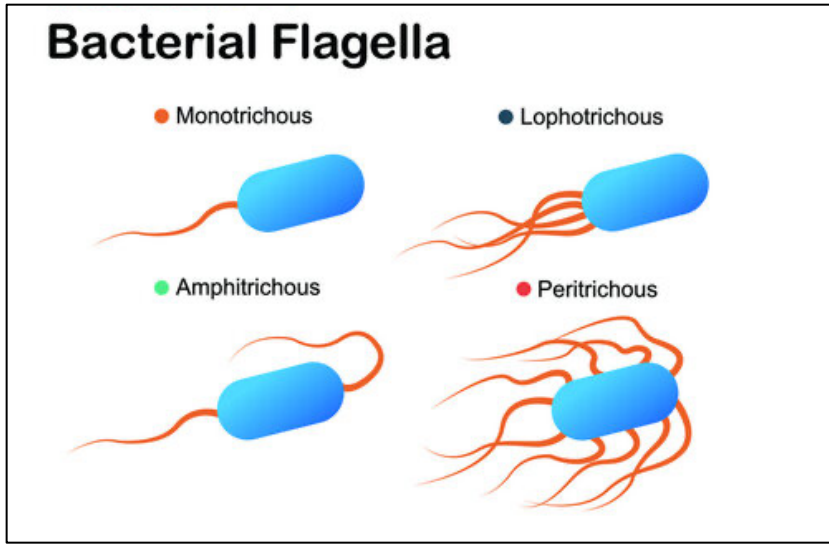
Flagella vary both in number and arrangement according to two general patterns

(A) In a **polar** arrangement, the flagella are attached at one or both ends of the cell.

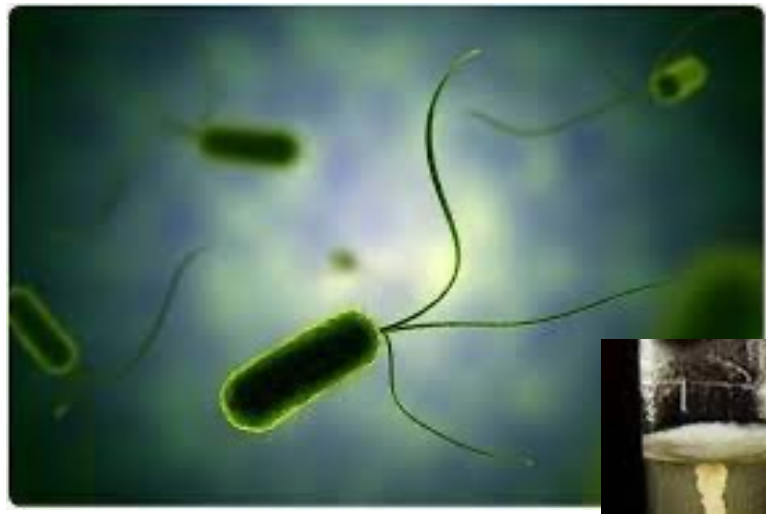
Three subtypes of this pattern are:

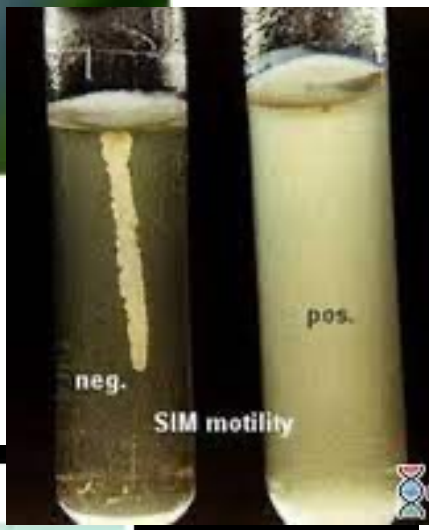
- **1-monotrichous** * with a single flagellum.
- 2- **amphitrichous** * with one flagellum in each side.
- 3- **lophotrichous** * with small bunches of flagella emerging from the same one site.

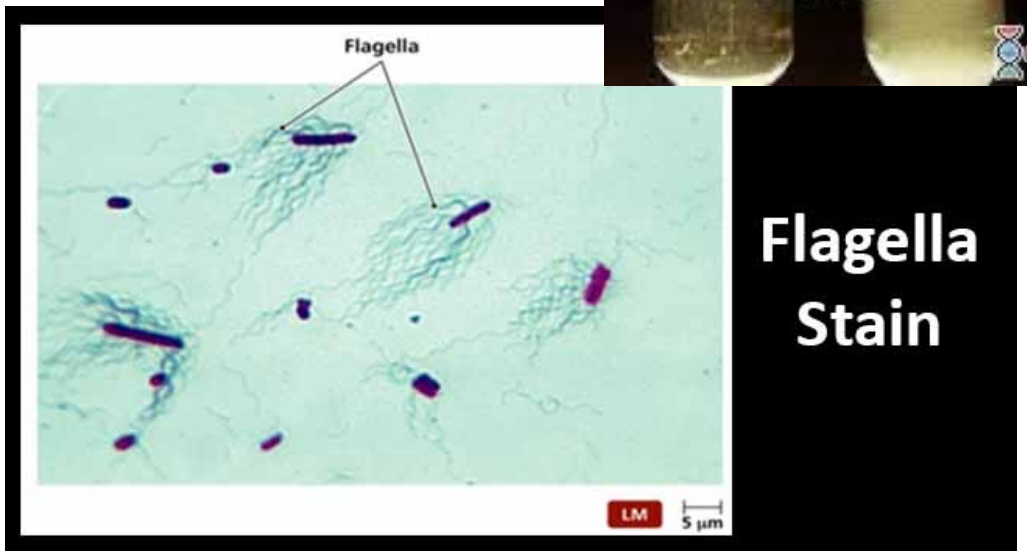
(B) In a **peritrichous** * arrangement, flagella are dispersed randomly over the surface of the cell.



- The presence of motility is used in the laboratory identification of various groups of bacteria.
- Special stains or electron microscope preparations must be used to see arrangement, because flagella are too minute to be seen in live preparations with a light microscope.

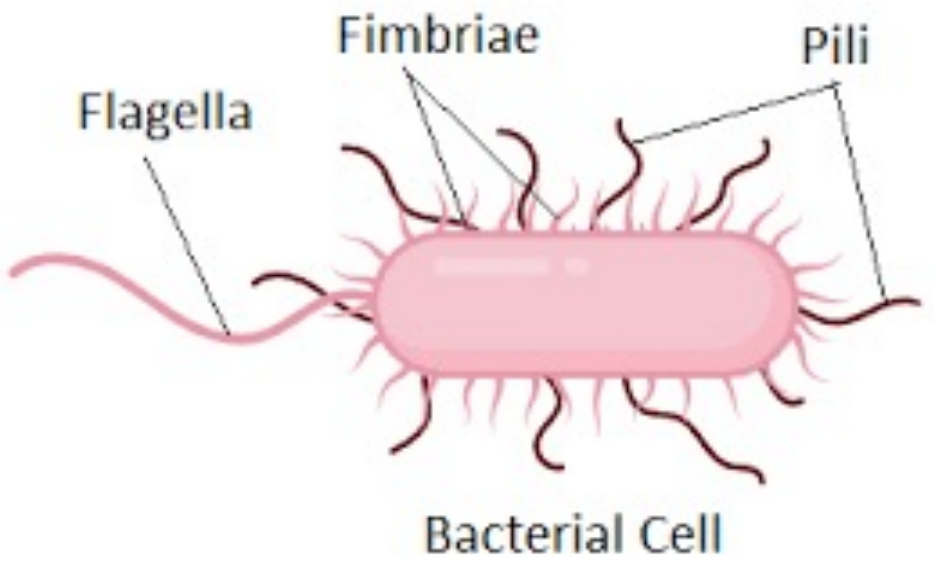




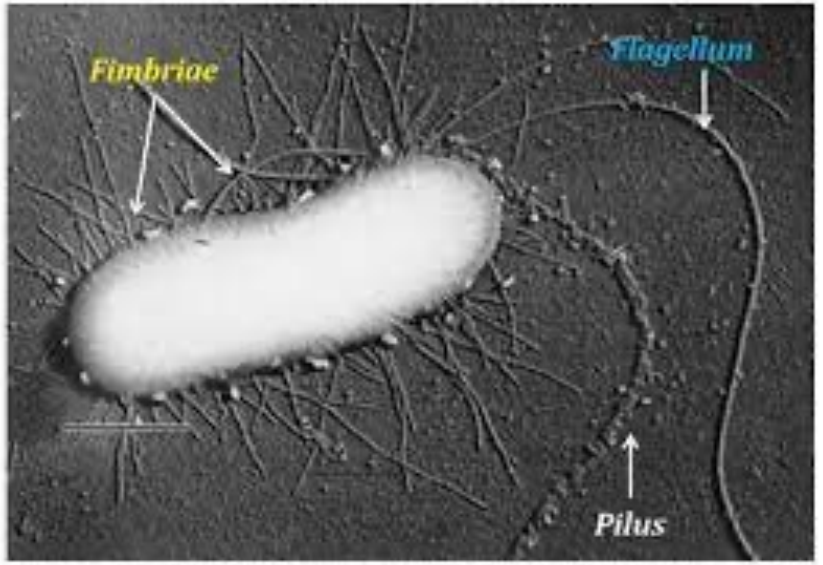


Fimbriae and Pili

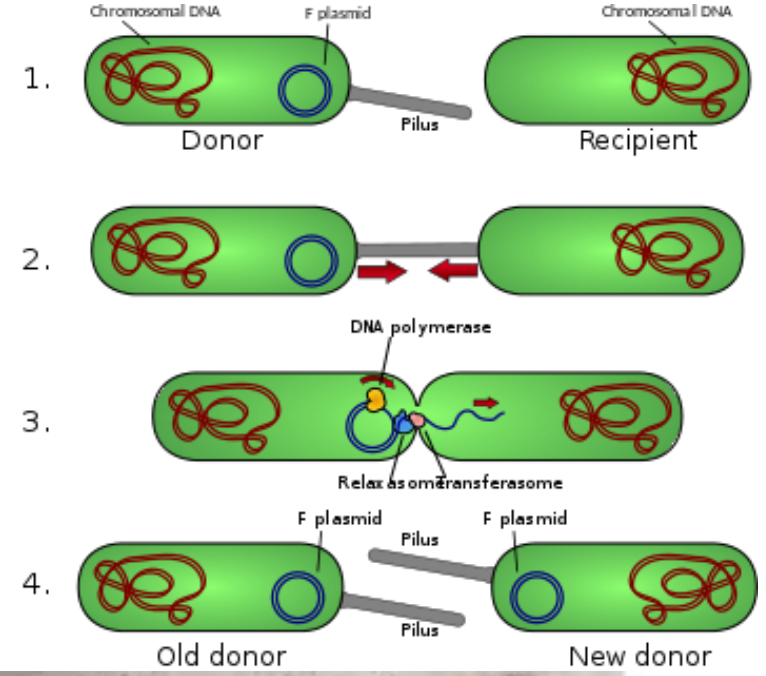
- The structures termed **fimbria** and **pilus** both refer to bacterial surface appendages that are involved in interactions with other cells but do not provide locomotion.

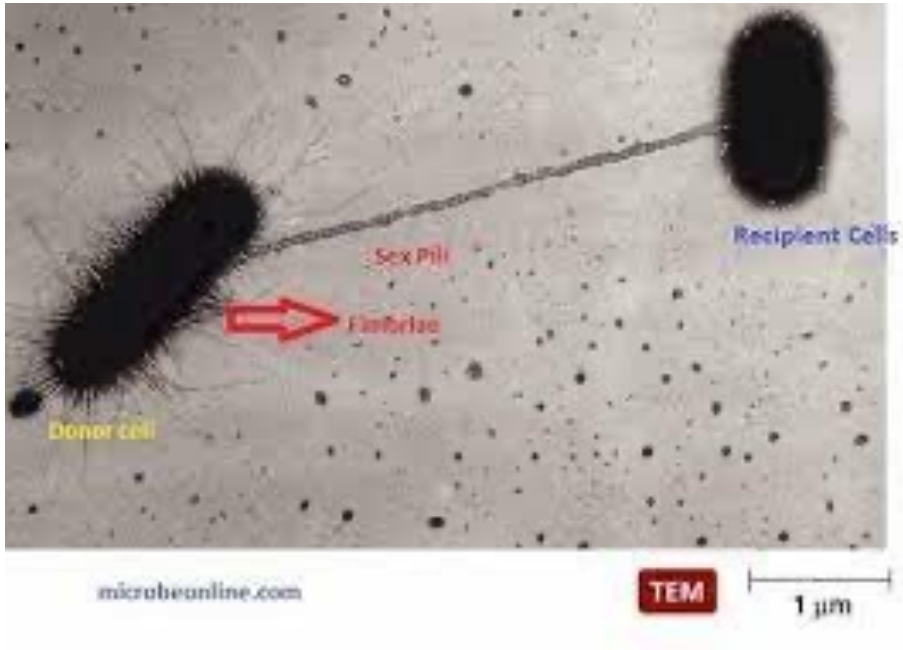


- **Fimbriae** are small, bristle like fibers emerging from the surface of many bacterial cells **.**
- Compose of protein. Fimbriae have an **inherent tendency** to stick to each other and to surfaces.
- They may be responsible for the mutual clinging of cells that leads to **biofilm formation** and other thick aggregates of cells on the surface of liquids and for the microbial colonization of solid surfaces such as, teeth, rocks and glass.
- Some pathogens can colonize and infect host tissues because of a tight adhesion between their fimbriae and epithelial cells **.** For example, the gonococcus (agent of gonorrhoea) colonizes the genitourinary tract, and *Escherichia coli* colonizes the intestine by this means.



- **Pilus** (also called a *sex pilus*) is an elongate, rigid tubular structure made of a special protein, *pilin* .
- So far, true pili have been found only on gram-negative bacteria, where they are utilized primarily in conjugation which involves a transfer of DNA from one cell to another.





Other Bacterial Surface Structures

- Glycocalyx (slime layer)

The glycocalyx is a loose shield of polysaccharide coating that covers the outer surface of many bacteria, protects them from dehydration and loss of nutrients and allows bacteria to adhere firmly to the various structures, e.g. oral mucosa, teeth, heart, and catheters, and contribute to the formation of biofilms.

Slime Layer

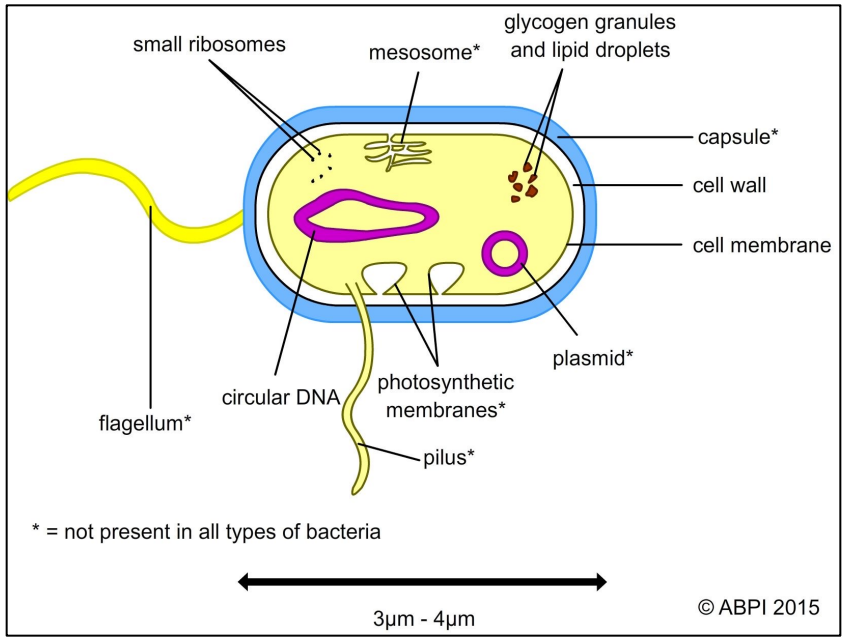
- **Capsule**

An amorphous, gelatinous layer (usually more substantial than the glycocalyx) surrounds the entire bacterium.

It composed of polysaccharides and sometimes proteins. The sugar components of the polysaccharides vary in different bacterial and frequently determine the serological type within a species.

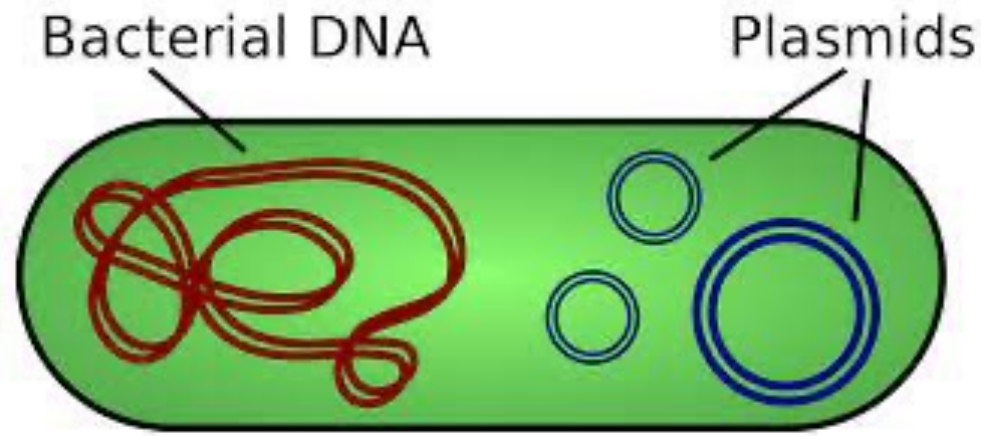
Contents of the Cell Cytoplasm

- ***Bacterial Chromosomes and Plasmids:***
- The hereditary material of most bacteria exists in the form of a single chromosome consisting of a circular, **double stranded** DNA molecule**.** By definition, bacteria do not have a true nucleus. Their DNA is not enclosed by a nuclear membrane but instead is aggregated in a central area of the cell called the **nucleoid.** The chromosome is actually an extremely long molecule of DNA that is tightly coiledto fit inside the cell compartment.
- Arranged along its length are genetic units (about 2000 genes) that carry information required for bacterial maintenance and growth. many bacteria contain other, nonessential pieces of DNA called plasmids.



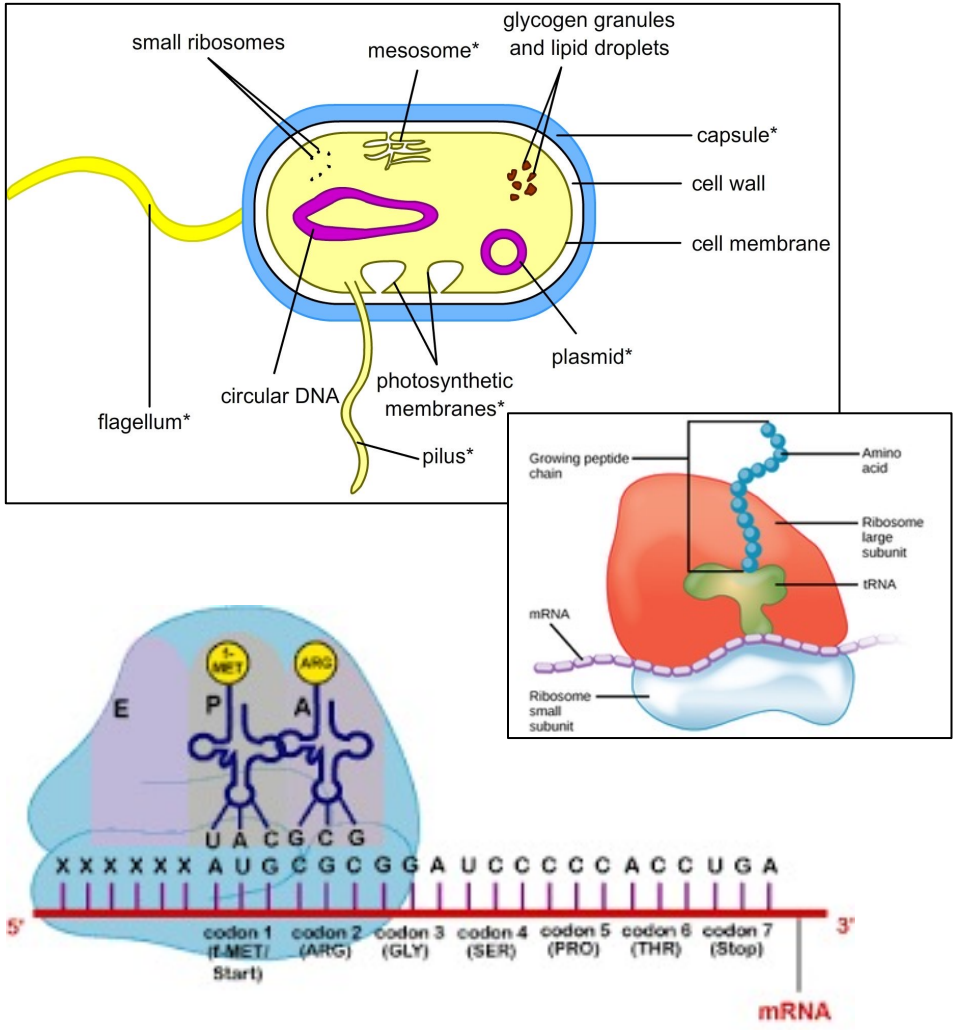
Plasmids

- A **plasmid** is a small DNA molecule within a cell that is physically separated from a chromosomal DNA and can replicate independently. They are most commonly found as small circular, double-stranded DNA molecules in bacteria; however, plasmids are sometimes present in archaea and eukaryotic organisms. In nature, plasmids often carry genes that may benefit the survival of the organism, for example antibiotic resistance.



Ribosomes: Sites of Protein Synthesis

- A bacterial cell contains thousands of **ribosomes,** which are made of RNA and protein., ribosomes show up as fine, spherical specks dispersed throughout the cytoplasm that often occur in chains (polysomes). Many are also attached to the cell membrane. Chemically, a ribosome is a combination of a special type of RNA called ribosomal RNA, or rRNA (about 60%), and protein (40%). They fit together to form factory where protein synthesis occurs.



Inclusions, or Granules: Storage Bodies

- **Inclusion bodies**, sometimes called **elementary bodies**, are nuclear or cytoplasmic aggregates of stable substances, usually proteins.
- Some inclusion bodies contain condensed, energy-rich organic substances, such as glycogen and poly b-hydroxybutyrate (PHB), within special single-layered membranes.
- **Granules,** contain crystals of inorganic compounds and are not enclosed by membranes.

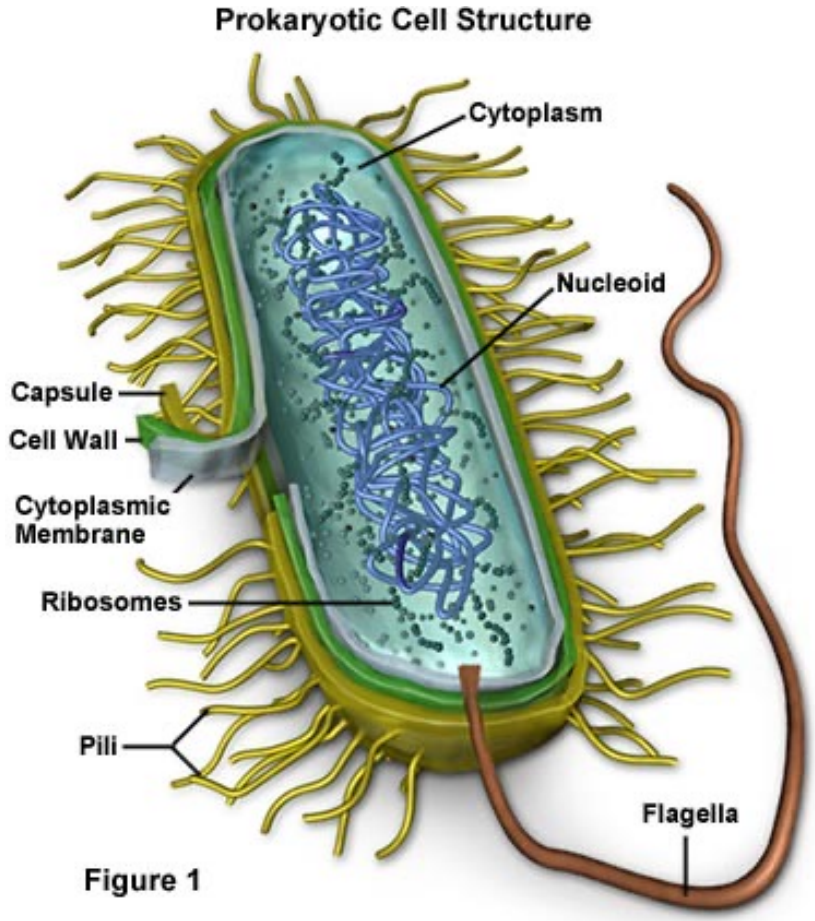


Figure 1

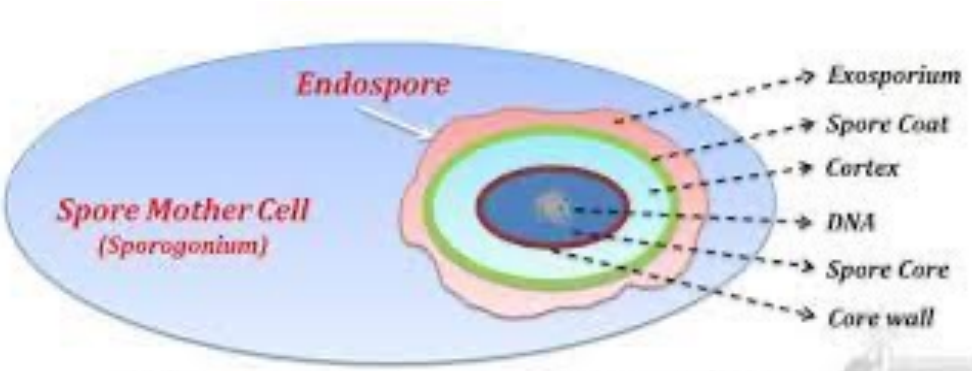
Bacterial Endospores:

An **endospore** is a dormant, tough, and non-reproductive structure produced by certain bacteria for withstanding hostile conditions and facilitating survival. (e.g. endospores produced by *Bacillus, Clostridium)*.

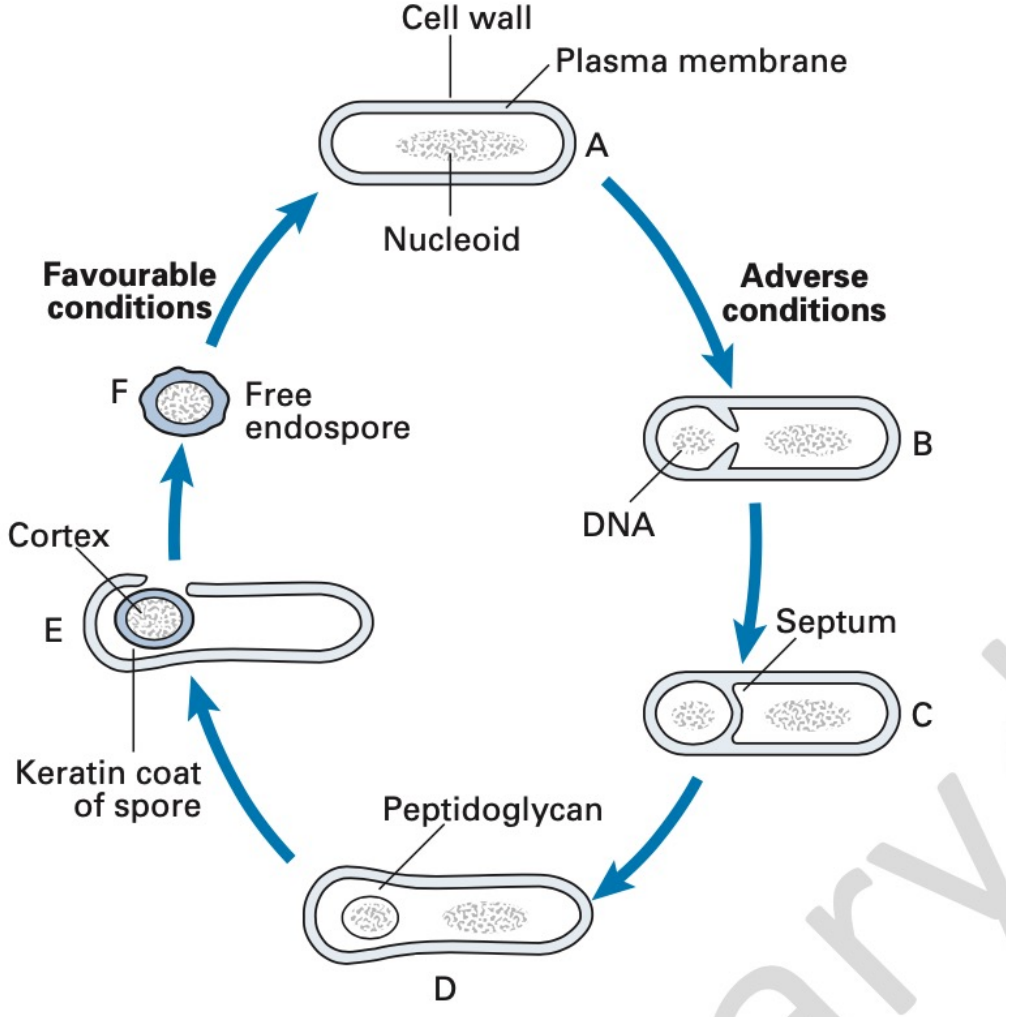
These bacteria have a two-phase life cycle that shifts between a **vegetative cell** and an **endospore.** The vegetative cell is the metabolically active and growing phase. When exposed to certain environmental signals, it forms an endospore by a process termed **sporulation.** The spore exists in an inert, resting condition that is capable of high resistance and very long-term survival.

- The spore contains bacterial DNA, a small amount cytoplasm, cell membrane, peptidoglycan, very little water and a thick keratin like coat. This coat is remarkably resistant to heat, dehydration, radiation and chemicals. Once formed, the spore is metabolically inert, and can remain dormant for many years. Bacterial endospores can be called either terminal or subterminal spores depending on their position inside the bacterial cell. When appropriate conditions supervene (e.g. water, nutrients), there is enzymatic degradation of the coat, and the spore transforms into a metabolizing, reproducing bacterial cell once again



Bacterial Endospore- Diagrammatic

Bacterial Endospores Formation



The cycle of sporulation. (**A**) Vegetative cell; (**B**) ingrowth of cytoplasmic membrane; (**C**) developing forespore; (**D**) forespore completely cut off from the cell cytoplasm; (**E**) development of cortex and keratin spore coat; (**F**) liberation of spore and conversion to vegetative state under favourable conditions.

Bacterial physiology

Dr. Mohammed Radhi

Microbial Growth

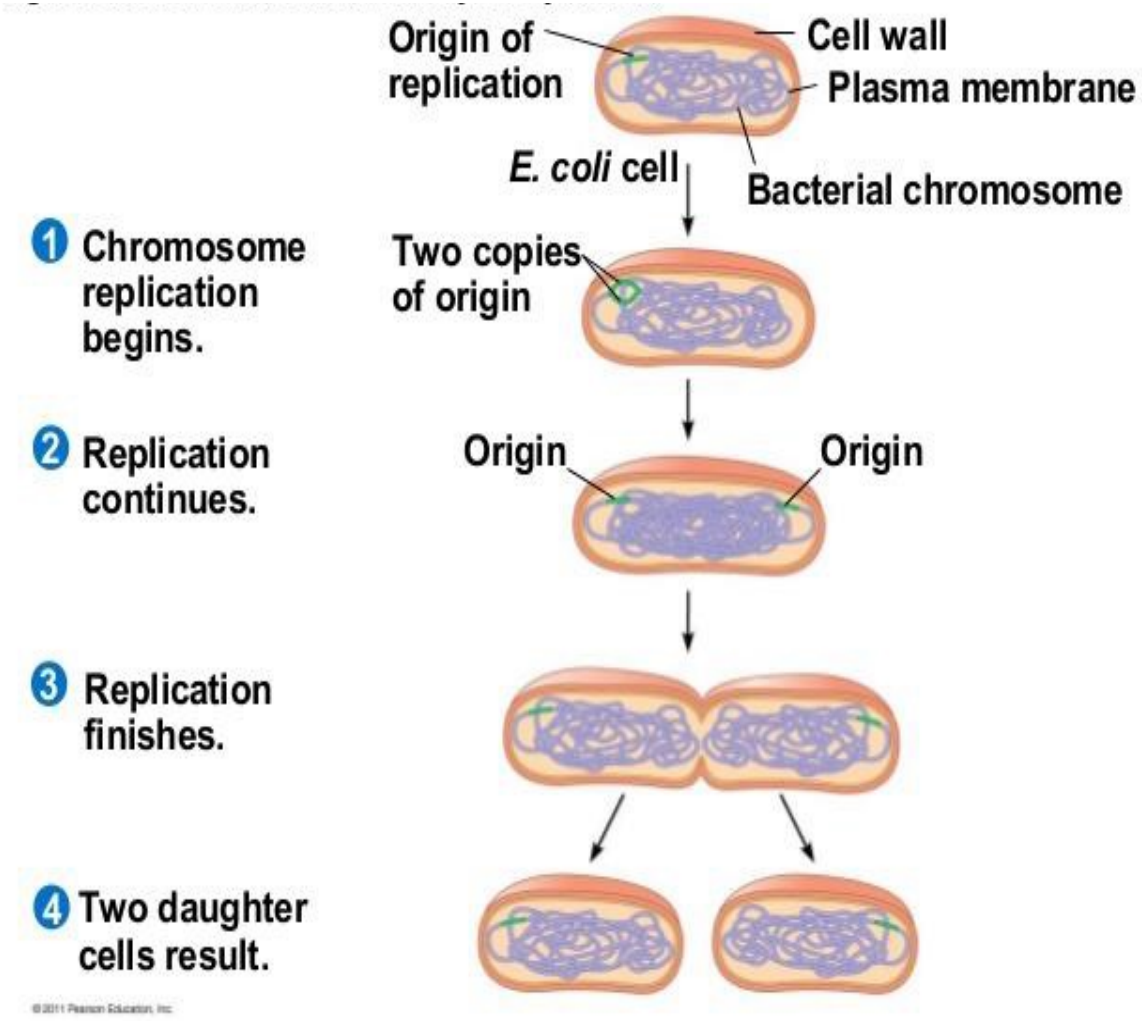
- When microbes are provided with nutrients and the required environmental factors, they become metabolically active and grow.

- Growth takes place on two levels.

-Cell synthesizes new cell components and increases its size.

-The number of cells in the population increases.

- The size of population is increased due to the bacterial cell multiplication by cell division. This has tremendous importance in microbial control, infectious disease, and biotechnology.
- The division of a bacterial cell occurs mainly through binary, or transverse, fission. During binary fission, the parent cell enlarges, duplicates its chromosome, and forms a central transverse septum that divides the cell into two daughter cells. This process is repeated at intervals by each new daughter cell in turn; and with each successive round of division, the population increases.



Bacterial Nutritional requirements

- Bacterial requirements for growth include oxygen, hydrogen and carbon), inorganic ions and organic nutrients.
- **Hydrogen** is usually obtained from water, and **oxygen** is obtained from atmosphere or from water where it is found in dissolved state.
- **Carbon:** according to their ability to synthesize essential metabolism (obtained carbon), bacteria can be classified into the following types:

A- Autotrophs:- These bacteria are able to synthesize their own organic food from inorganic substances. They use carbon dioxide for obtaining carbon

B- Heterotrophs:-Microbes obtain their carbon from organic compound, such as sugar, protein and lipids.

- **Inorganic ions;** Nitrogen, sulphur, phosphate, potassium and some other elements.
- **Organic nutrients**:- Organic nutrients are required in small amounts by cells because they play specific roles in biosynthesis.

Growth factors are organized into three categories:

1-purines and pyrimidines: required for synthesis of nucleic acids (DNA and RNA)

2-amino acids: required for the synthesis of proteins

3-vitamins: needed as coenzymes and functional groups of certain enzymes

Factors that modify bacterial growth

- **pH:-**
- according to their acidity requirements bacteria can be classified into:

1-Acidophiles:- Microorganisms which grow at pH (3-5).
2- Neutrophiles:- Microorganisms which grow best at neutral pH (6-8)
3- Alkaliphiles:- Microorganisms which grow best under alkaline conditions pH as high as 10.5.

Moisture:-

- Water is needed for the growth and reaction of metabolism like glycolysis and protein synthesis, various nutrient must be in a soluble form to facilitate diffusion into the cell. In the absence of the water some bacteria will form a spore for continue its survival.

Gas requirement:-

- Microorganisms fall into several groups with respect to the effect of oxygen on their growth and metabolism:
  1. **Obligate aerobes**
  - use and require oxygen as electron acceptor
  - have respiratory enzymes and lack the capacity for fermentations
  - examples: Pseudomonas, some Bacillus
  2. **Obligate anaerobes**
  - do not need or use O2 as a nutrient. In fact, O2 is a toxic substance, which either kills or inhibits their growth. Obligate anaerobic procaryotes may live by fermentation, anaerobic respiration
  - examples: Clostridium, Bacteroides

3. **Facultative organisms** •
- are organisms that can switch between aerobic and anaerobic types of metabolism. Under anaerobic conditions (no O2) they grow by fermentation or anaerobic respiration, but in the presence of O2 they switch to aerobic respiration.
- examples: all Enterobacteriaceae (*E.coli*), some Bacillus

- 4. **Aerotolerant anaerobes**
  - grow either with or without oxygen, but metabolism remains fermentative and do not use oxygen
  - examples: Enterococcus faecalis, some Lactobacillus

5-Microaerophilec

-these bacteria grow well under low oxygen concentration

-examples: *Campylobacter fetus*

Temperature:-

The temperature range at which organism grow best is called **optimum temperature.** In human parasitic organism optimum temperature ranges between 30° C and 37° C. there are three groups of bacteria as regard to the temperature:-

- 1- Psychrophilic:-

The bacteria is growing between 0° C and 25° C. they are mostly soil and water bacteria

- 2- Mesophilic:-

Some bacteria grow between 20° C and 44° C this group include bacteria producing disease.

3- Thermophilic:-

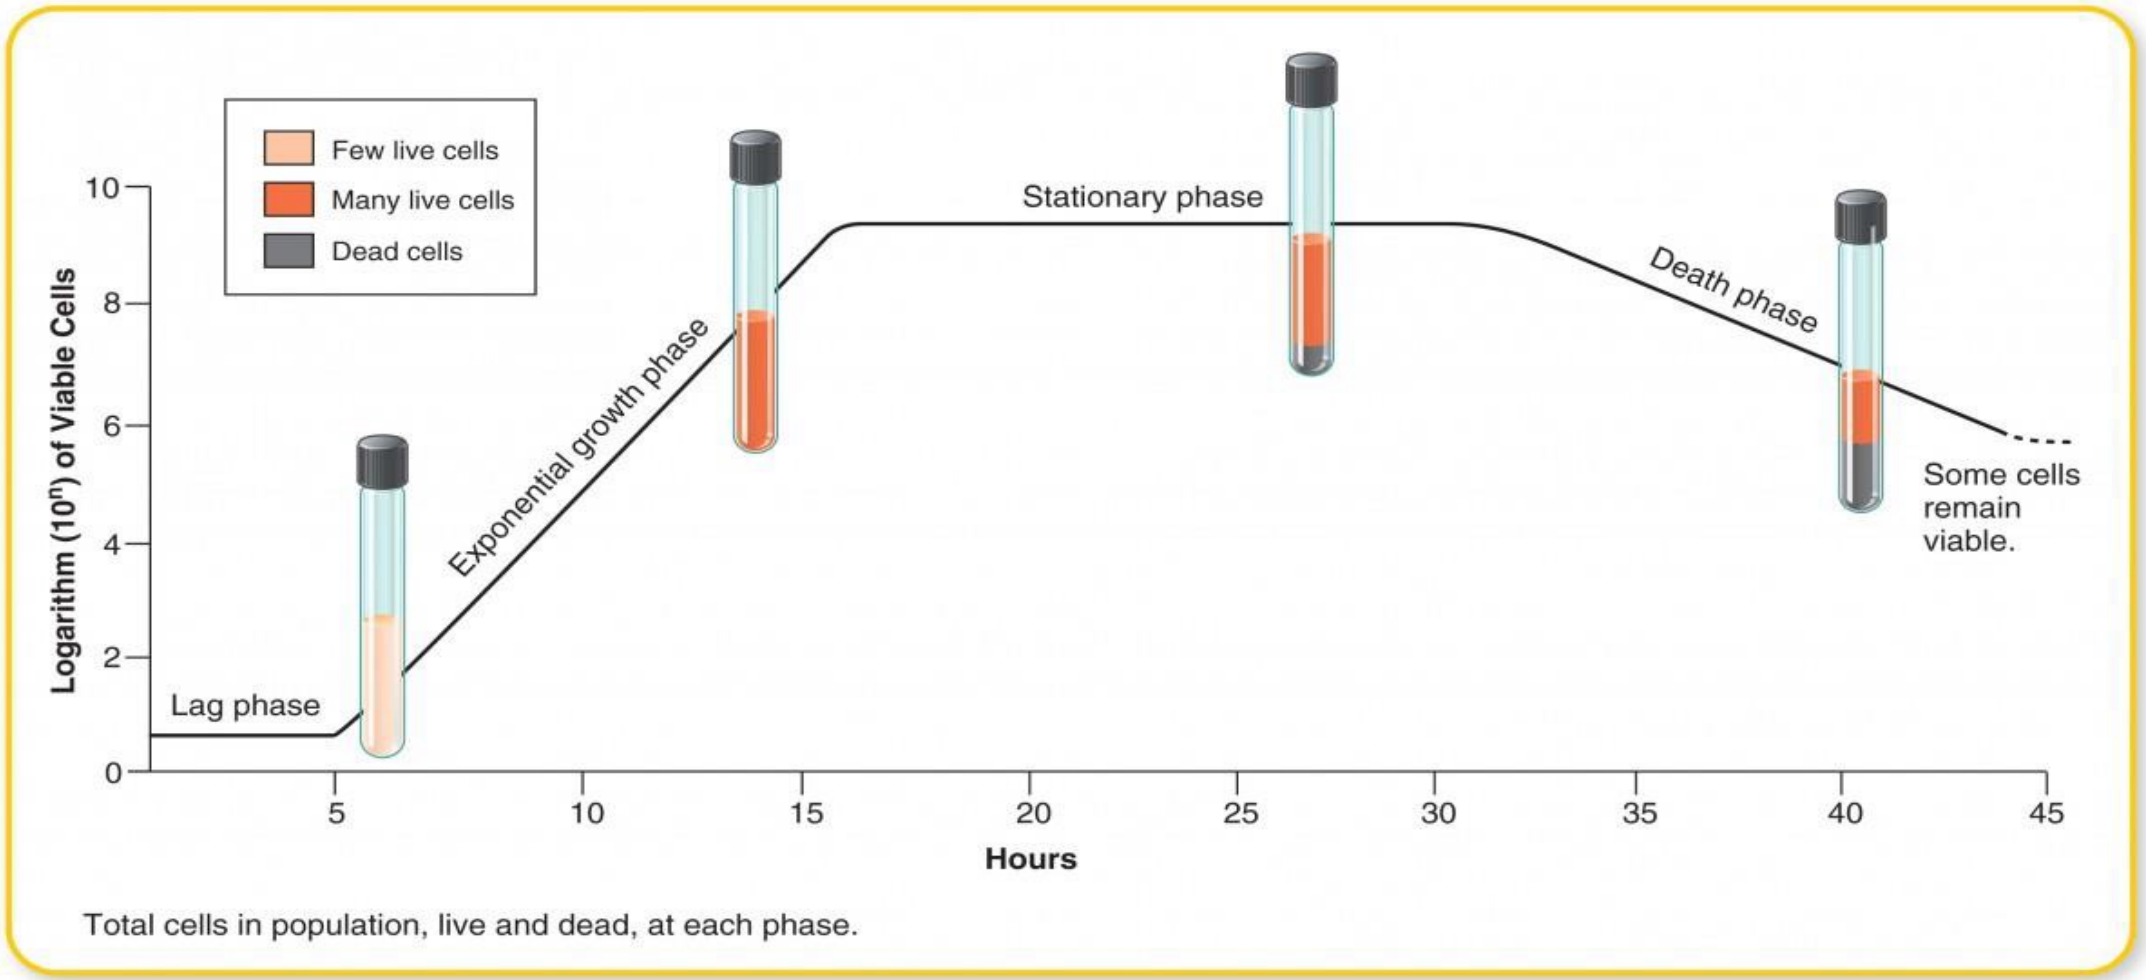
- The bacteria can grow between 50 and 80° C this bacteria will survive after pasteurization processes of milk.

The Rate of Population Growth

- The time required for a complete fission cycle—from parent cell to two new daughter cells—is called the **generation**, or **doubling time**. In bacteria, each new fission cycle or generation increases the population by a factor of 2, or doubles it.
- The length of the generation time is a measure of the growth rate of an organism. The average bacterial generation time is 30 to 60 minutes under optimum conditions.
- The shortest generation times average 5 to 10 minutes, and longer generation times require days.
- Some bacterial species, for example, *Mycobacterium leprae* (the cause of Hansen's disease), has a generation time of 10 to 30 days.
- Most pathogenic bacteria have relatively short doubling times. *Salmonella enteritidis* and *Staphylococcus aureus*, bacteria that cause food-borne illness, double in 20 to 30 minutes.

Stages in the Normal Growth Curve

- Data from an entire growth period of 3 to 4 days typically produce a curve with a series of phases termed the lag phase, the exponential growth (log) phase, the stationary phase, and the death phase .



Total cells in population, live and dead, at each phase.

The death phase

The decline in the growth rate is caused by several factors.

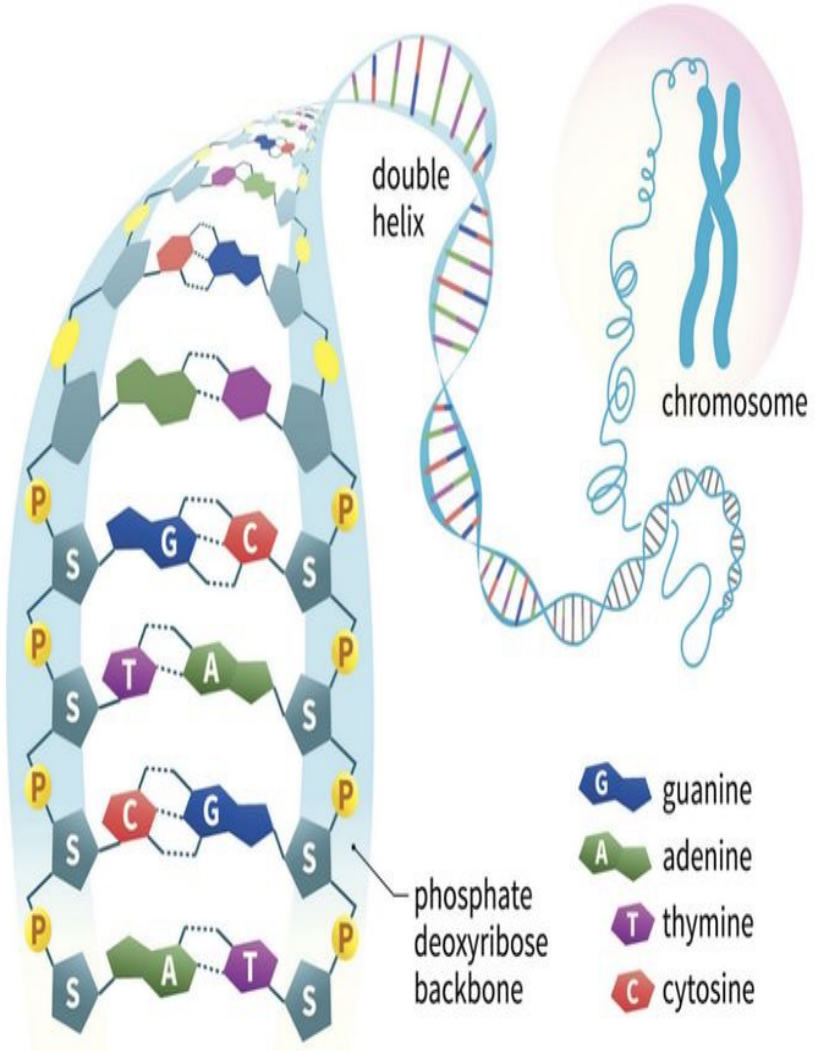
- 1-Depletion of nutrients and oxygen.
- 2-Increased cell density often causes an accumulation of organic acids and other toxic biochemicals.

Cells begin to die at an exponential rate and most are unable to multiply. The curve now dips downward as the death phase begins. The speed with which death occurs depends on the relative resistance of the species and how toxic the conditions are, but it is usually slower than the exponential growth phase.

Bacterial genetics

- Genetics is the study of the inheritance and variation. All bacterial characteristics are encoded in DNA. DNA or **Deoxyribonucleic acid** is a molecule composed of two chains (made of nucleotides) that coil around each other to form a double helix carrying all the genetic instructions that used in the growth, development, functioning and reproduction of all known living organisms and many viruses. DNA and ribonucleic acid (RNA) are nucleic acids; alongside proteins, lipids and complex carbohydrates (polysaccharides), which all are the four major types of macromolecules that are essential for all known forms of life.
- The two DNA strands are also known as polynucleotides since they are composed of simpler monomeric units called nucleotides.

- Each DNA nucleotide is composed of one of four nitrogen-containing nucleobases (cytosine[C], guanine [G], adenine [A] or thymine [T]), a sugar called deoxyribose, and a phosphate group.
- The nucleotides are joined to one another in a chain by covalent bonds between the sugar of one nucleotide and the phosphate of the next, resulting in an alternating sugar-phosphate backbone. The nitrogenous bases of the two separate polynucleotide strands are bound together, according to base pairing rules (A with T and C with G), with hydrogen bonds to make double-stranded DNA.



- The DNA of most bacteria is contained in a single circular molecule, called the bacterial chromosome. The chromosome, along with several proteins and RNA molecules, forms an irregularly shaped structure called the nucleoid. This sits in the cytoplasm of the bacterial cell.

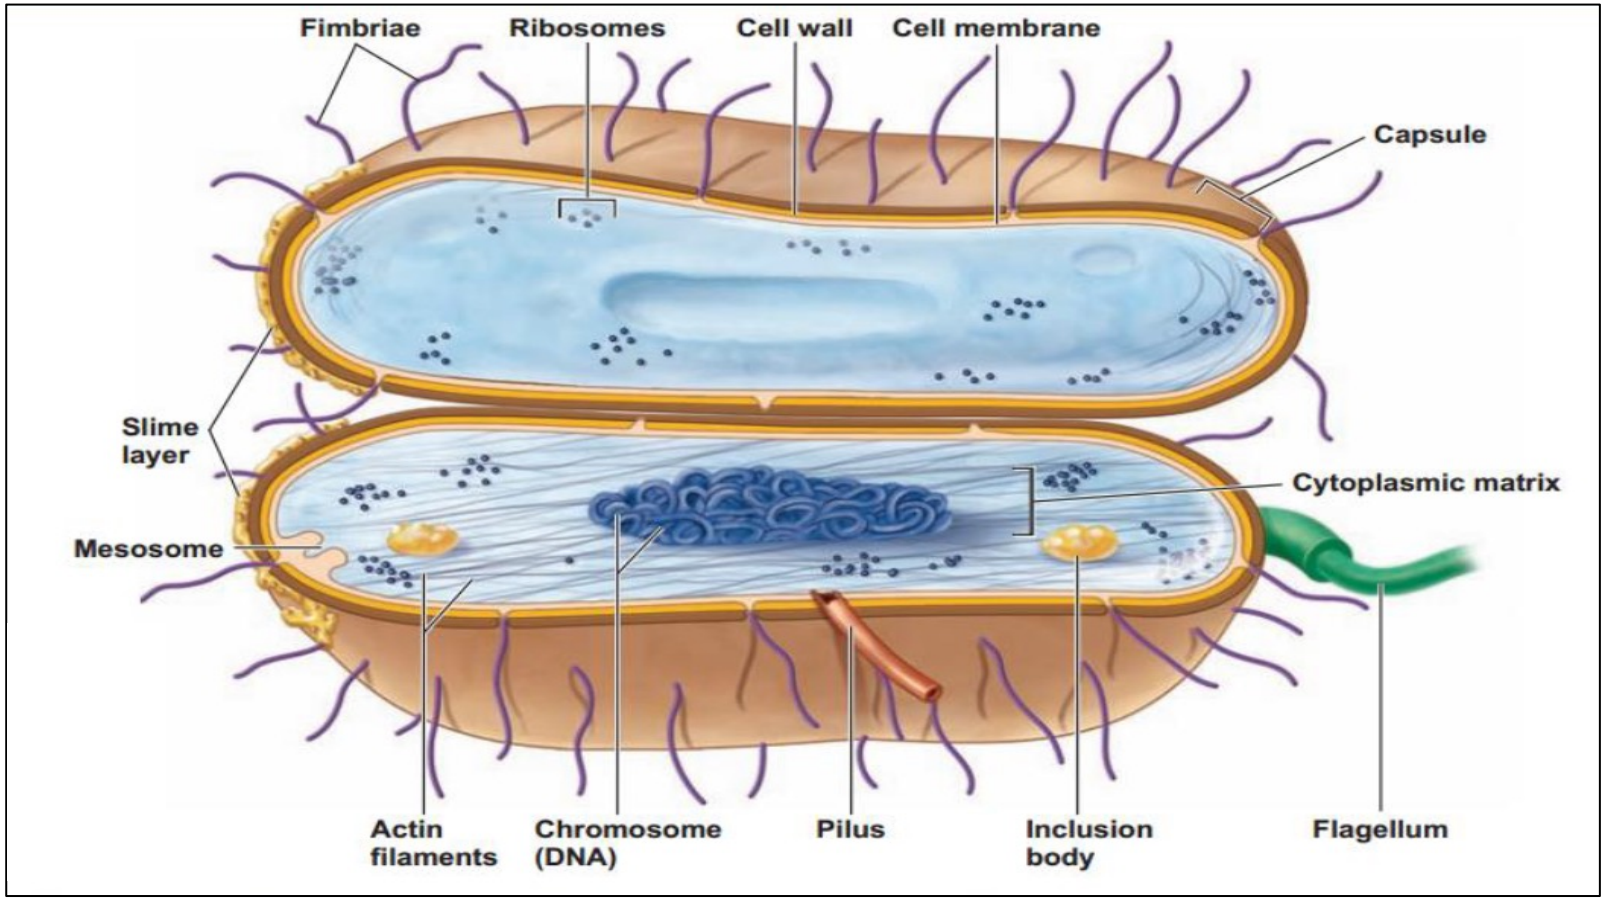


Figure 8. 3D structure of the bacterial cell.

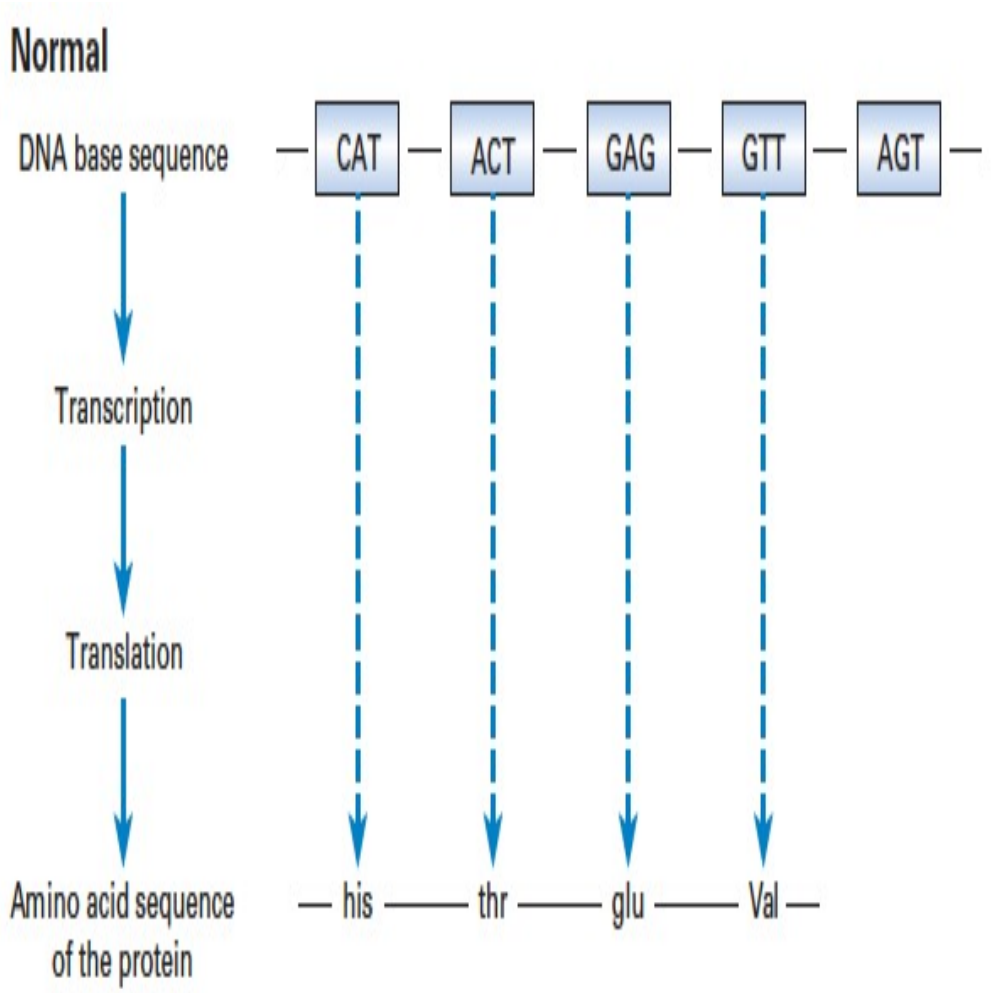
Genes

- The genetic code of bacteria is contained in a series of units called genes. As the normal bacterial chromosome has one copy of each gene, bacteria are called **haploid** organisms (higher organisms which contain two copies of the gene called diploid).
- A gene is a chain of purine (A&G) and pyrimidine (T&C) nucleotides. the genetic information is encoded in triple nucleotide groups or codons. Each codon codes for specific amino acid or regulatory sequence, e.g. starts and stope codons. In this way the structural genes determine the sequence of amino acids that form the protein, which is the gene product.



Genetic variation in bacteria

Genetic variation can occur as a result of mutation or gene transfer.

A- Mutation

- Mutation is a change in the base sequence of DNA, as a consequence of which different amino acids are incorporated into a protein, resulting in an altered phenotypes. There are three types of DNA mutations.

1- Base substitution : this occurs during DNA replication when one base is inserted in place of another. And it has two types

-Missense mutation: when the base substitution results in a codon that instructs a different amino acid to be inserted.

-nonsense mutation: when the gene mutation stops its protein synthesis.

2- Frame shift mutation: which occur when one or more base pair are added or deleted that resulted in production of inactive protein because of the production of wrong amino acids.

- Insertion : the insertion of additional pieces of DNA.

B-Gene transfer

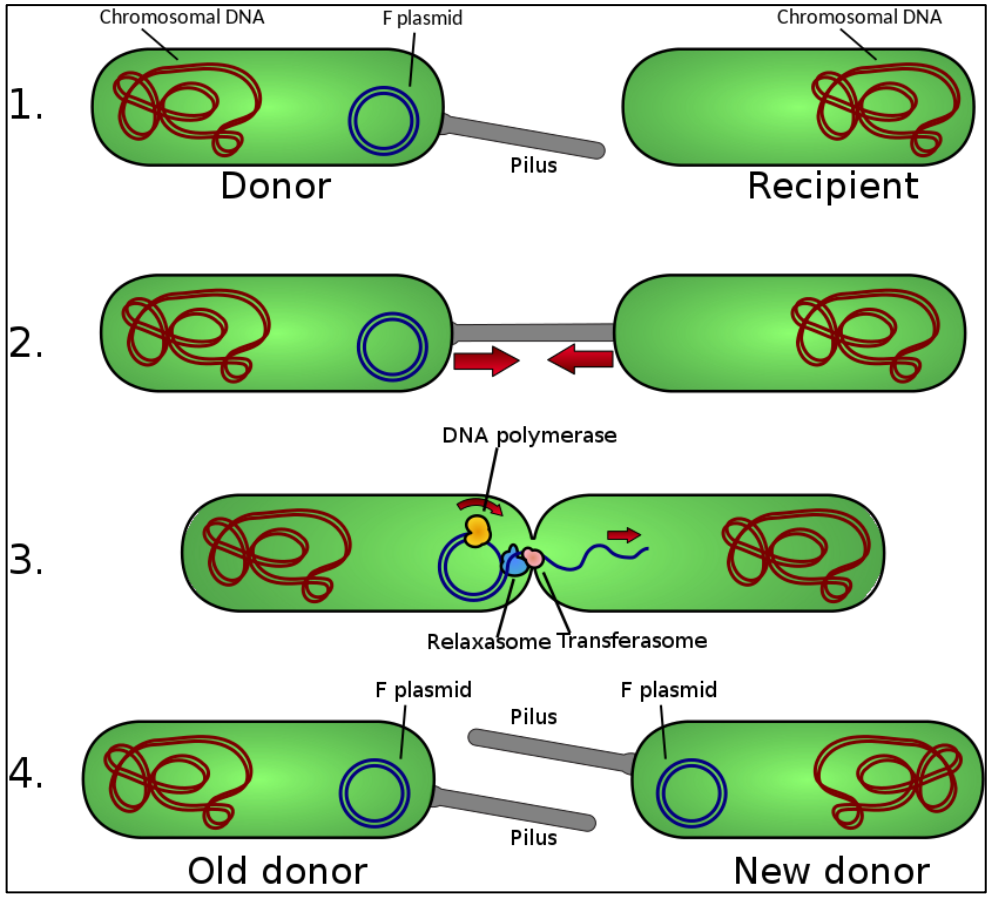
the transfer of genetic information can occur by:

- Conjugation
- Transduction
- Transformation
- Transposition

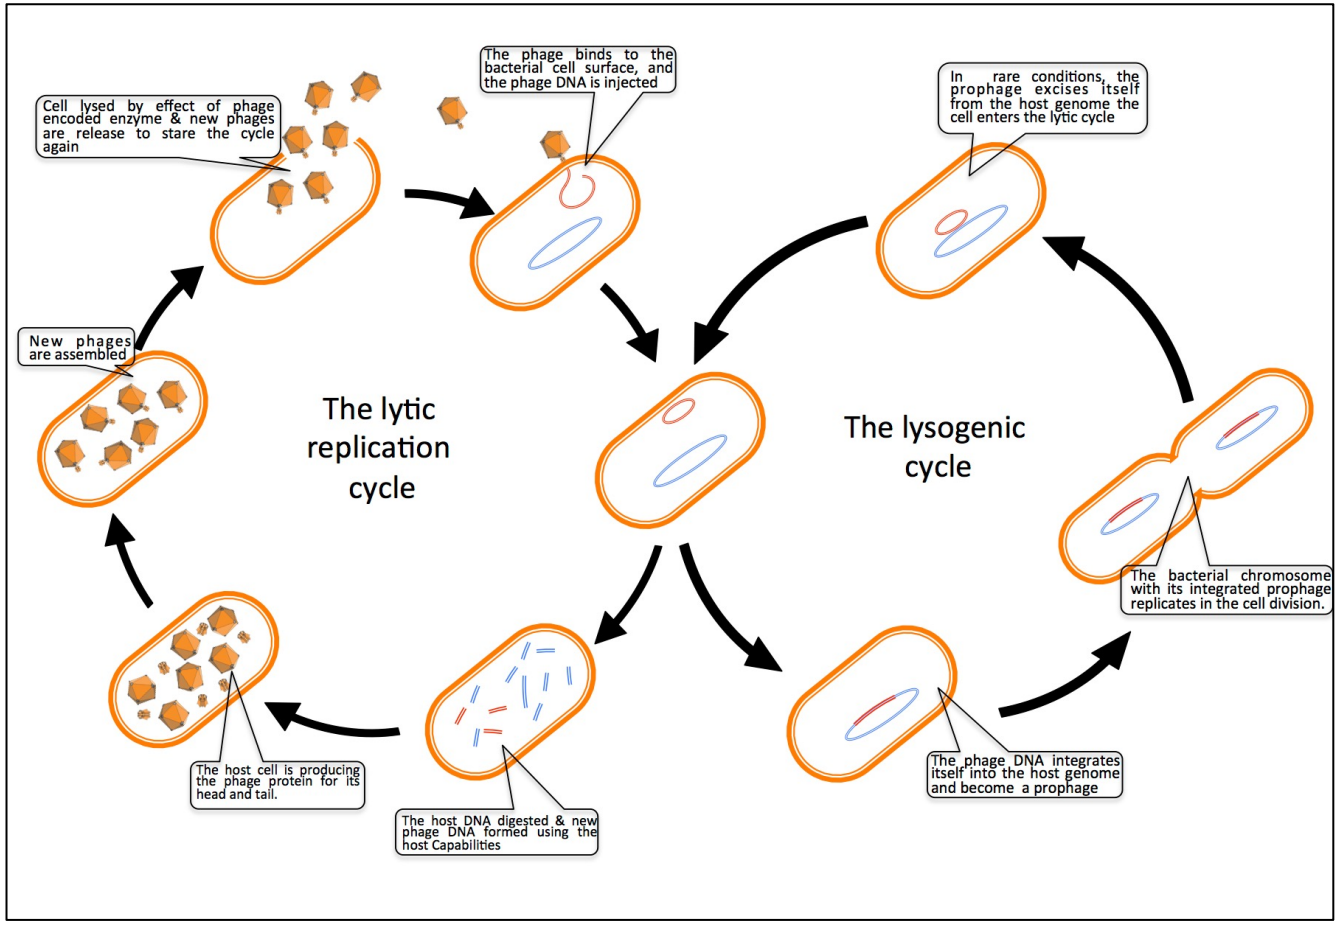
Conjugation

- Bacterial conjugation is the transfer of genetic material between bacterial cells by direct cell-to-cell contact (mating of two cells) or by a bridge-like connection between two cells. This takes place through pilus (Pili in plural).
- It is one of horizontal gene transfer mechanisms. During conjugation the *donor* cell provides a conjugative or mobilizable genetic element that is most often a plasmid or transposon. Most conjugative plasmids have systems ensuring that the *recipient* cell does not already contain a similar element.
- The genetic information transferred is often beneficial to the recipient. Benefits may include antibiotic resistance, xenobiotic tolerance or the ability to use new metabolites. The mating process is controlled by an F (fertility) plasmid ,carrying genes for the proteins required for mating including pilin, which forms pilus.

- Donor cell [cell carrying F factor or (F+)] produces pilus.
- Pilus attaches to recipient cell and brings the two cells together.
- The mobile plasmid is cleaved enzymatically and a single strand of DNA is then transferred to the recipient cell.
- Both cells synthesize a complementary strand to produce a double stranded circular plasmid and are able to reproduce pili; both cells are now viable donor for the F-factor.

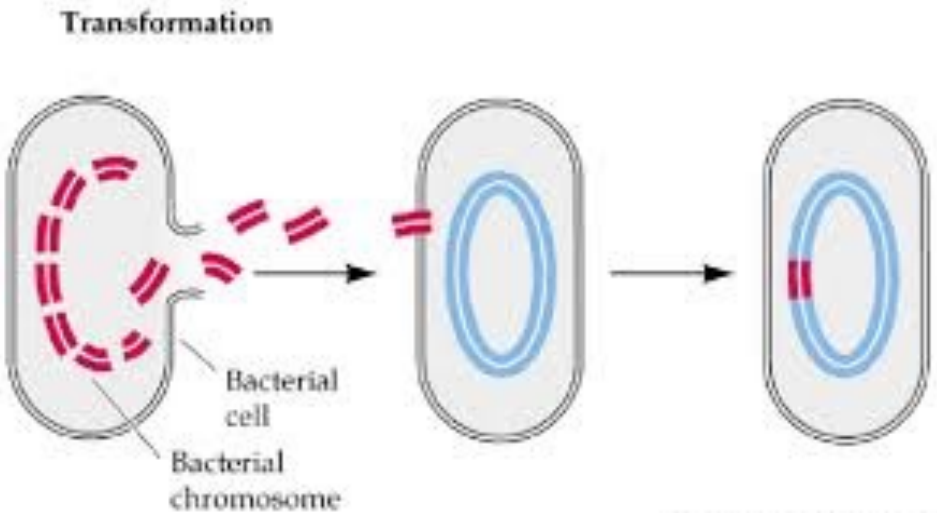


Transduction



Transformation

- This is the transfer of exogenous of bacterial DNA from one cell to another. It occurs in nature when dying bacteria release their DNA, which is than taken up by recipient cells and recombined with the recipient cell's DNA.



Transposition

- This occurs when transposable element moves from one DNA site to another within the same genome of the same organism.
- The simplest transposable elements, called; insertion sequences, are less than 2 kilobases in length and encodes enzymes (transposase) required for “DNA jumping” from one site to another.

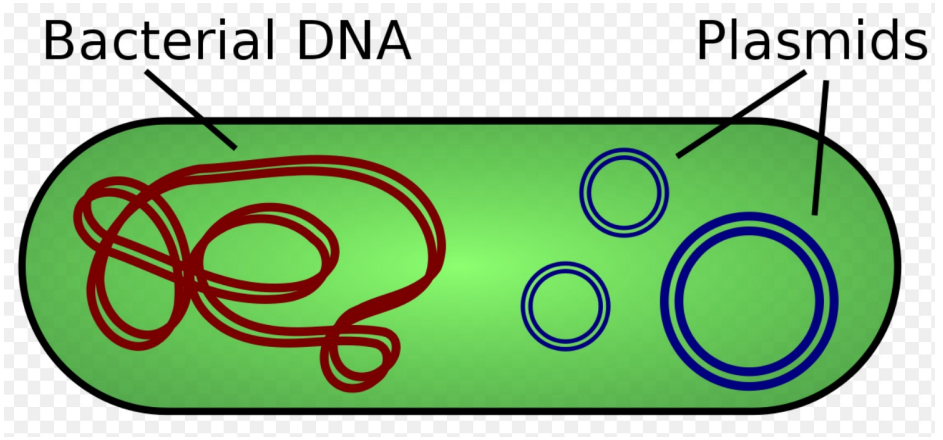
DNA recombination

- The transferred DNA from the donor cell to the recipient cell is integrated into the host genome by a process called DNA recombination. There are two types of DNA recombination depends on DNA homology between the two recombinant molecules:
- Homologous recombination
- Nonhomologous recombination.

Plasmids

- A **plasmid** is a small DNA molecule within a cell that is physically separated from a chromosomal DNA and can replicate independently. They are most commonly found as small circular, double-stranded DNA molecules in bacteria; however, plasmids are sometimes present in archaea and eukaryotic organisms. In nature, plasmids often carry genes that may benefit the survival of the organism, for example antibiotic resistance.

- While the chromosomes are big and contain all the essential genetic information for living under normal conditions, plasmids usually are very small and contain only additional genes that may be useful to the organism under certain situations or particular conditions. Artificial plasmids are widely used as vectors in molecular cloning, serving to drive the replication of recombinant DNA sequences within host organisms. In the laboratory, plasmids may be introduced into a cell via transformation.



Bacterial Pathogenicity

Infection: is the invasion of the human body tissue by disease causing agents, their multiplication, and the reaction of host tissues to the infectious agents and the toxin they produce.

Mixed infection: Several microbes grow simultaneously at the infection site.

Disease: Any deviation from health, disruption of a tissue or organ caused by microbes or their products.

CARRIER: A Person or animal with asymptomatic infection that can be transmitted to another susceptible person or animal.

Human body defenses

There are two kinds of body defenses against microbial infections:

- **humoral immunity** the aspect of immunity that is mediated by macromolecul , such as secreted antibodies , complement proteins and certain Antimicrobial peptide.
- **Cell-mediated immunity** is an Immune response that does not involve Antibody but rather involves the activation of body immunity cells like Phagocytes, Antigen -specific Cytotoxic T-lymphocytes.

According to its way of living bacteria can be classified to

1. **Nonpathogenic:** A microorganism that does not cause disease.
2. **Opportunistic pathogen:** An agent capable of causing disease only when the host's resistance is impaired (e.g. when the patient is "immunocompromised).
3. **Pathogenic bacteria:** is parasitic bacteria that are the causative agents of bacterial infections.
4. **Saprophytic bacteria:** which live freely in the soil and feed on decaying organic matters.
5. **Commensals:** Are parasitic bacteria live on external or internal surfaces of the body without causing disease, these bacteria may even be beneficial to the host e.g. commensals of the gut digest polysaccharides and are source of certain vitamins, these bacterial flora also compete with pathogenic bacteria for nutrition thus inhibiting their growth.

Bacterial Pathogenicity:

refers to the ability of an organism to cause disease, using its virulence factors**.** **Virulence** usually refers to the degree of pathogenicity within a group or species of microorganisms. virulence of a microorganism is not generally attributable to a single factor, but depends on several parameters that are related to the organism, the host, and the dynamic interaction between them. Bacterial virulence, can be measured by bacterial **infectivity** (their ability to initiate an infection) and the **severity** of the condition produced.

In the lab, Virulence can be designated as LD_{50} or ID_{50} (These values are determined by inoculation of laboratory animals):

the LD_{50} (50% lethal dose) is the number of organisms needed to kill half the hosts, and ID_{50} (50% infectious dose) is the number needed to cause infection in half the hosts.

Pathogenicity depends on:

1- Virulence factors (Adherence factors, Invasiveness, Toxin production).

2- Number of initial organisms.

3- Immune status.

Table 5.2 Examples of surface virulence factors which interfere with host defences

Organism	Virulence factor	Used in vaccine
Bacteria		
Streptococcus pneumoniae	Polysaccharide capsule	Yes
Streptococcus pyogenes	M protein	No
Staphylococcus aureus	Protein A	No
Neisseria meningitidis	Polysaccharide capsule	Yes
Haemophilus influenzae	Polysaccharide capsule	Yes
Klebsiella pneumoniae	Polysaccharide capsule	No
Escherichia coli	Protein pili	No
Salmonella typhi	Polysaccharide capsule	No
Mycobacterium tuberculosis	Mycolic acid cell wall	No
Fungi		
Cryptococcus neoformans	Capsule	No

STAGES OF PATHOGENICITY

1-Transmission

2-Attachment (adhesion, adherence).

3-Colonization and multiplication of microorganism.

4-Avoidance of host defense mechanisms like phagocytosis.

5-Damage of host cells by:

A- Invasiveness.

B -Toxin production.

C- Both of them.

TRANSMISSION Most infections are acquired by transmission from external sources, they are **exogenous** in origin. Others are caused by members of the normal flora behaving as opportunist pathogens, i.e. they are **endogenous** in origin. Transmission can be by:

- inhalation- the airborne route
- ingestion - faecal contamination of food and water.
- Inoculation - by sexual contact, contaminated needles, skin contact, blood transfusions or biting insects.

There are four important portals (or gates) of pathogens

1- Skin.

2- Respiration.

3- Gastrointestinal tract.

4- Genitourinary tract.

Table 5.1 Portals of entry of some common pathogens

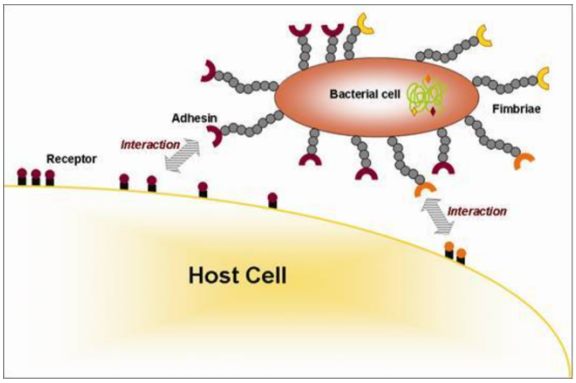
Portal of entry	Pathogen	Disease
Skin	*Clostridium tetani*	Tetanus
	Hepatitis B virus	Hepatitis B
Respiratory tract	*Streptococcus pneumoniae*	Pneumonia
	Neisseria meningitidis	Meningitis
	Haemophilus influenzae	Meningitis
	Mycobacterium tuberculosis	Tuberculosis
	Influenza virus	Influenza
	Rhinovirus	Common cold
	Epstein–Barr virus	Infectious mononucleosis
Gastrointestinal tract	*Shigella dysenteriae*	Dysentery
	Salmonella typhi	Typhoid fever
	Vibrio cholerae	Cholera
	Hepatitis A virus	Infectious hepatitis
	Poliovirus	Poliomyelitis
Genital tract	*Neisseria gonorrhoeae*	Gonorrhoea
	Treponema pallidum	Syphilis
	Human immunodeficiency virus (HIV)	Acquired immune deficiency syndrome (AIDS)
	Candida albicans (fungus)	Vaginitis

Adherence to host surfaces.

Adherence is the first step in the infection. Unless organisms have the ability to stick or adhere to host surfaces they will be unable to cause infection. Some bacteria and fungi have specialized structures or produce substances that facilitate their attachment to the surface cells (e.g. dentures, artificial heart valves), thereby enhancing their ability to colonize and cause disease. These adherence mechanisms are critical for organisms that attach to mucous membranes; mutants that lack these mechanisms are often non-pathogenic (e.g. the hair-like pili or Fimbriae, of *Neisseria gonorrhoeae* and *Escherichia coli* mediate their attachment to the urinary tract epithelium; the extracellular polysaccharides of *Streptococcus mutans* help it adhere to enamel surfaces).

Adherence factors.

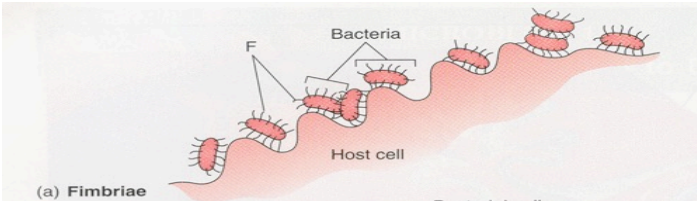
1-Fimbriae: Are the most common adhesion molecules e.g. *Neisseria gonorrhoeae* and *E coli* mediate the attachment to cell surfaces.



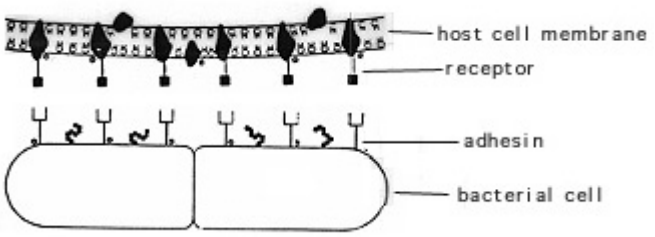
2- The **filamentous haemagglutinin adhesin (FHA)** is a large, filamentous Protein that serves as a dominant attachment factor for adherence to host Cilium Epithelium of the Respiratory tract.

3-Exopolysaccarides.Present on the surface of some-gram positive bacteria are also involving in adhesions.

4- Flagella act as adhesion *in Vibrio cholerae* and *Campylobacter jejani*.



5- In addition to above types of adherence factors **Specific adherence** involves permanent formation of many specific lock- key bonds between complementary molecules on each cell surface.

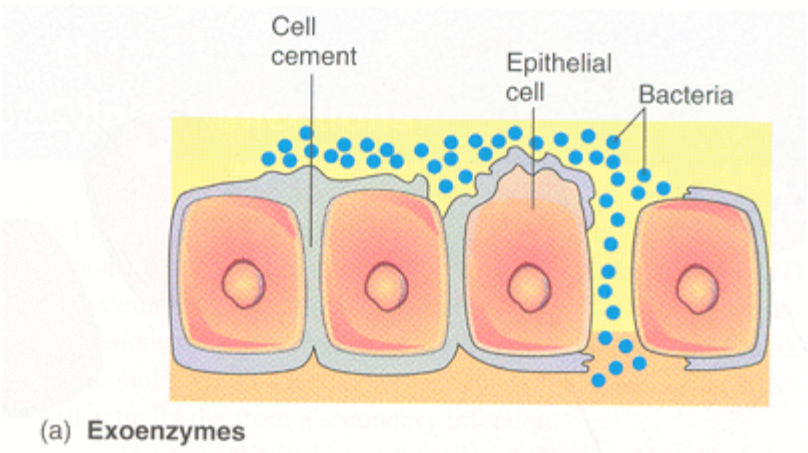


Colonization and invasion:

For many pathogenic bacteria, the initial interaction with host tissues occurs at a mucosal surface and then colonization is started. This allows the establishment of infection that may remain localized or may subsequently spread to other tissues in a process called **invasion**. Cell invasion confers the ability to avoid humoral host defence mechanisms .

INVASIVENESS

These are mechanisms that give bacteria its ability to invade tissues, multiply and spread rapidly (bacterial invasion). Invasiveness of bacteria plays a critical role in their pathogenesis by secretion of bacterial enzymes. Most are enzymes affecting physical barriers like tissue matrices and cell membranes. In this way, the bacterium can quickly spread through extracellular spaces.



(a) Exoenzymes

A few examples are:

a hemolysin or **listeriolysin O**: Which injects into the membrane of the vacuole and causes the formation of pores (e.g. that caused by *Listeria monocytogenes)* then enters the cytoplasm of the cell, where it continues to grow and multiply, after escaping the toxic environment of the phagolysosome.

Coagulase: Produced by *Staphylococcus aureus,* accelerates the formation of a fibrin clot (from fibrinogen). It helps protect the organisms from phagocytosis by walling off the infected area and by coating the organisms with a fibrin layer.

Collagenase : It breaks down collagen fibers & promote spread of infection.

Streptokinase and **staphylokinase :** produced from Group A streptococci and staphylococci that hydrolyze fibrin clots, which also facilitate the spread of organisms in the tissues.

Immunoglobulin A (IgA) protease: Degrades protective IgA on mucosal surfaces, allowing organisms such as *N gonorrhoeae, Haemophilus injluenzae* and *Streptococcus pneumoniae* to adhere to mucous membranes.

AGGRESSINS

In order to survive and multiply within the host, many organisms produce a variety of substances that allow them to avoid host defence mechanisms. These substances, termed aggressins, include capsules and extracellular slime substances, surface proteins, surface carbohydrates, enzymes, toxins, and other small molecules. The capsular structures of some bacteria enable the organisms to avoid phagocytosis by preventing interaction between the bacterial cell surface and phagocytic cells or by concealing bacterial cell surface components that would otherwise interact with phagocytic cells or complement and lead to ingestion. Some organisms produce capsules that are structurally similar to host tissues and, therefore, are not recognized as foreign by the body defense mechanisms. Organisms that possess capsules behave as aggressins include S. *aureus, S. pneumoniae, N. meningitidis, H. influenzas* type b, *K. pneumoniae* .

TOXIGENICITY

Toxin is a protein or conjugated protein produced by some pathogenic bacteria that is highly poisonous for other living organism. The ability of microorganism to produce a toxin that contributes to the development of disease called **toxigenicity.** Toxins are of two categories: endotoxins and exotoxins.

Endotoxins

Endotoxins are the cell wall lipopolysaccharides of Gram-negative bacteria (both cocci and bacilli) and are not actively released from the active cell, it is released after the cell death. Endotoxins cause fever, shock and other generalized symptom s.

It is an outer membrane chemical moiety consisting of three sections:

1-A toxic lipid (Lipid A) anchored in the outer membrane,

2-An immunogenic polysaccharide core, and

3-An O antigen proteins of oligosaccharides at the extracellular surface.

Exotoxins

Both Gram-positive and Gram-negative bacteria secrete exotoxins. Exotoxins in particular can cause disease in distant parts of the body as a result of diffusion of the toxin via systemic routes (e.g. tetanus bacillus infecting a lesion in the foot produces an exotoxin which causes 'lockjaw' or spasm of masseter muscles on the face).

Bacterial exotoxins can be broadly categorized as:

• neurotoxins

• enterotoxins

• miscellaneous exotoxins.

Neurotoxins. Tetanus toxin (produced by bacteria called *Clostridium tetan*i**)** , diphtheria toxin (by *Corynebecterium diphtheria*) and botulinum toxin (by Clostridium botulinum) are all neurotoxins and their action is mediated via neuronal pathways.

Enterotoxins. These toxins act on the gut mucosa and cause gastrointestinal disturbances. *Escherichia coli* enterotoxin is of two types: one heat-labile and one heat-stable.

Miscellaneous exotoxins. these exotoxins are produced by *Clostridium perfringens* and other species of clostridia that cause gas gangrene.

Antiphagocytic (Survival Inside of Phagocytes)

Many bacterial pathogens are rapidly killed once they are ingested by polymorphonuclear cells or macrophages. Some pathogens evade phagocytosis or leukocyte microbicidal mechanisms by adsorbing normal host components to their surfaces.

For example, *Staph..aureus* has surface protein A. Other pathogens have polysaccharide capsules that impede phagocytosis, e.g., *Streptococcus pneumoniae, N meningitidis.*

Streptococcus pyogenes (group A streptococci) have M protein, *N gonorrhoeae*(gonococci) have pili.

Most of these antiphagocytic surface structures show much antigenic heterogeneity. For example, there are more than 80 pneunococcal capsular polysaccharide types and more than 60 M protein types within group A *streptococci*.

Bacteria that can resist killing and survive or multiply inside of phagocytes are considered intracellular parasites. In this case, the environment of the phagocyte may be protecting bacteria during the early stages of infection or until they develop more virulence factors.

The role of bacterial biofilms

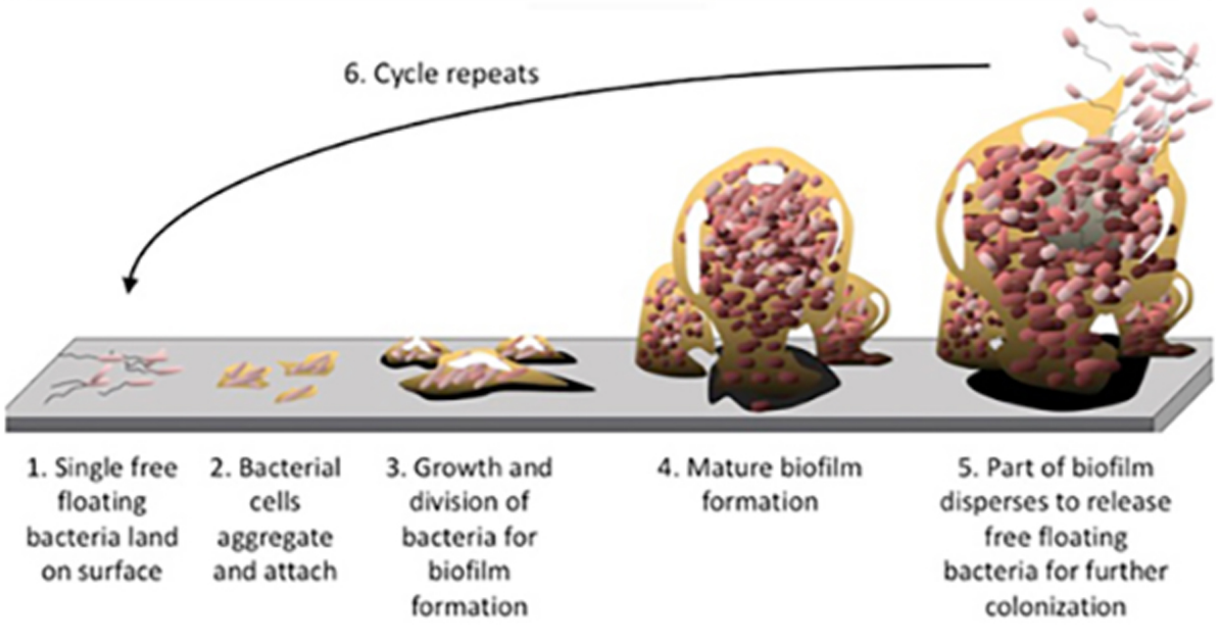
A biofilm is an aggregate of interactive bacteria attached to a solid surface or to each other and encased in an exopolysaccharide matrix. Biofilms form a slimy coat on surfaces and throughout nature. Bacteria of single species may coaggregate to form a biofilm. Fungi- including yeasts are occasionally involved.

Biofilms are:

- -formed when microbes adhere to each other and to the surface
- -each microbe secretes glycocalyx substances allowing other microbes to adhere; large mass is formed

the biofilm is resistant to disinfectants and antibiotics (outer layer protects inner layers), which makes serious problems for patients with catheters and surgical implants: serves as chronic reservoir.

Biofilms are important in human infections that are persistent and difficult to treat. A few examples include *Staphylococcus epidermidis* and *Staphylococcus aureus* infections of central venous catheters, eye infections such as occur with contact lenses and intraocular lenses, in dental plaque, and with *Pseudomonas aeroginosa* airway infections in cystic fibrosis patients.



Pathogenesis of viral infection

Pathogenesis is the process by which an infection leads to disease. Pathogenic mechanisms of viral disease include

(1) implantation of virus at the portal of entry,

(2) local replication,

(3) spread to target organs (disease sites), and

(4) spread to sites of shedding of virus into the environment.

Factors that affect pathogenic mechanisms are

(1) accessibility of virus to tissue,

(2) cell susceptibility to virus multiplication, and

(3) virus susceptibility to host defenses.

Virions (free viruses) implant onto living cells mainly via the respiratory, gastrointestinal, skin-penetrating, or urogenital routes although other routes can be used. The final outcome of infection may be determined by the dose and location of the virus as well as its infectivity and virulence.

Most virus types spread among cells extracellularly, but some may also spread intracellularly. Establishment of local infection may lead to localized disease and localized shedding of virus.

The incubation period is the time between exposure to virus and onset of disease. During this usually asymptomatic period, implantation, local multiplication, and spread (for disseminated infections) occur.

Depending on the balance between virus and host defenses, virus multiplication in the target organ may be sufficient to cause disease and death. (e.g. specific preference cells for rhinoviruses are upper respiratory epithelium and for human immunodeficiency virus (HIV) are CD4 T Lymphocytes)

Diverse viruses may be shed at virtually every site.

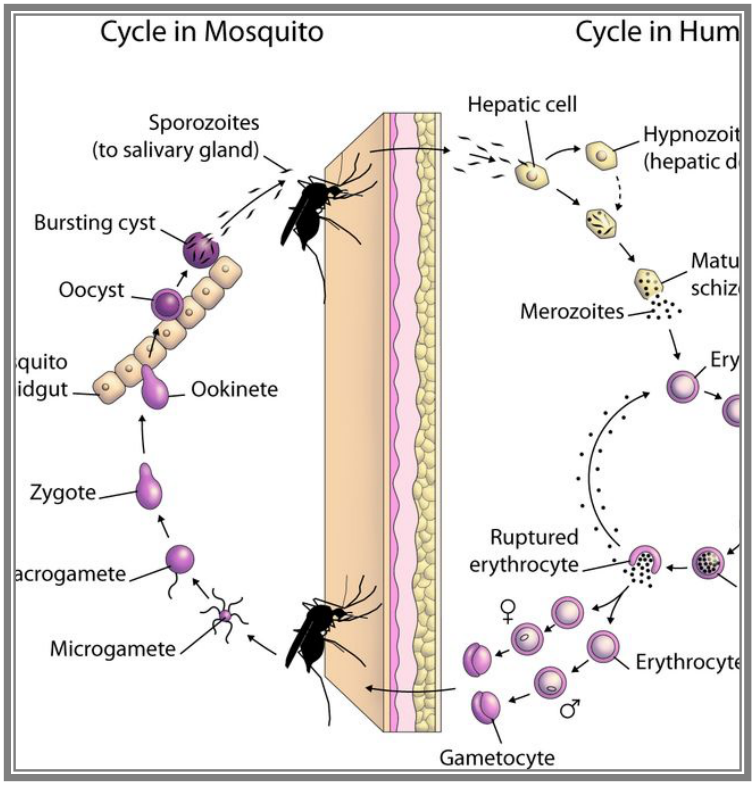
Pathogenesis of fungal infection

Fungal disease, particularly its life-threatening extreme, is relatively rare despite the some species of fungi present in the environment and on the human body surface. Most fungal infections appear to require a breach in host defenses in order to become established. Yeasts often cause mucosal inflammation following alteration of either vaginal or gastrointestinal flora. Dermatophytic fungi cause a variety of skin conditions but rarely cause more invasive disease in immunocompetent patients because they are restricted to the skin.

Pathogenesis of parasitic infections

Protozoal and helminth infections have a complex pathogenesis, which is best understood by referring to the parasite's life cycle. Some protozoal and helminth infections require transmission by a disease vector. The vector is often an arthropods. The development of disease depends on a three-way relationship between microorganism, vector and human victim in these infections.

In developed countries, parasitic infections are most common in international travelers, the sexually active, immunocompromised patients and poor people.



Life Cycle of Malaria Parasite

Opportunist infections

If an organism is capable of causing disease in an apparently healthy individual, it is clearly aggressively pathogenic. If it is normally incapable of causing disease but can do only when the human body immunity is compromised in some way, in this case infection called opportunist infection. These types of infections have a particular importance in hospitals patients and immunocompromised patients.

Oral Normal flora

Dr Mohammed Radhi

Normal flora of the human body

In a healthy human body, the internal tissues, e.g. blood, brain, muscle, etc., are normally free of microorganisms. However, the surface tissues are constantly in contact with environmental organisms and be colonized by various microbial species. The mixture of organisms regularly found at any anatomical site is referred to as the **normal flora**.

Normal flora is an aggregate of microorganisms that placed on the surface tissues which are constantly in contact with environmental atmosphere, i.e., skin and mucous membranes.

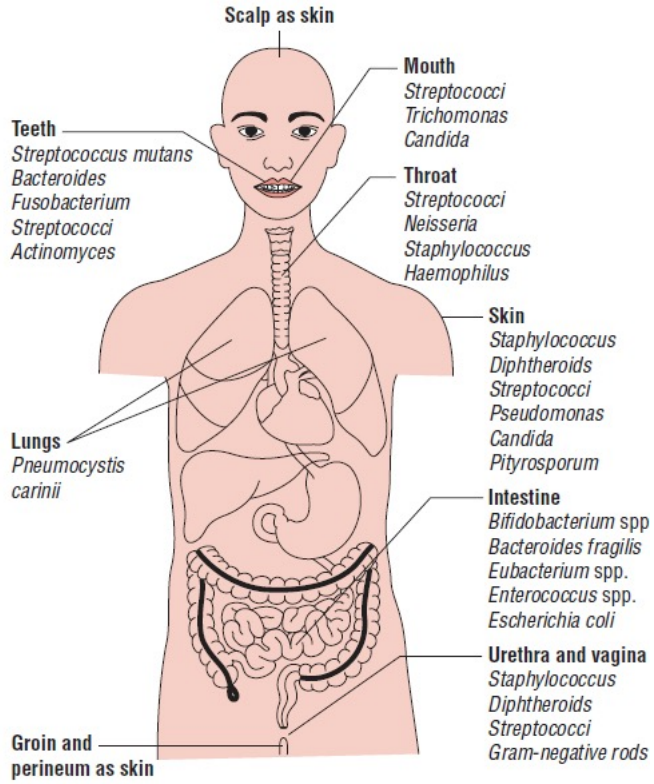


FIG. 75-1. Sites of microbial flora.

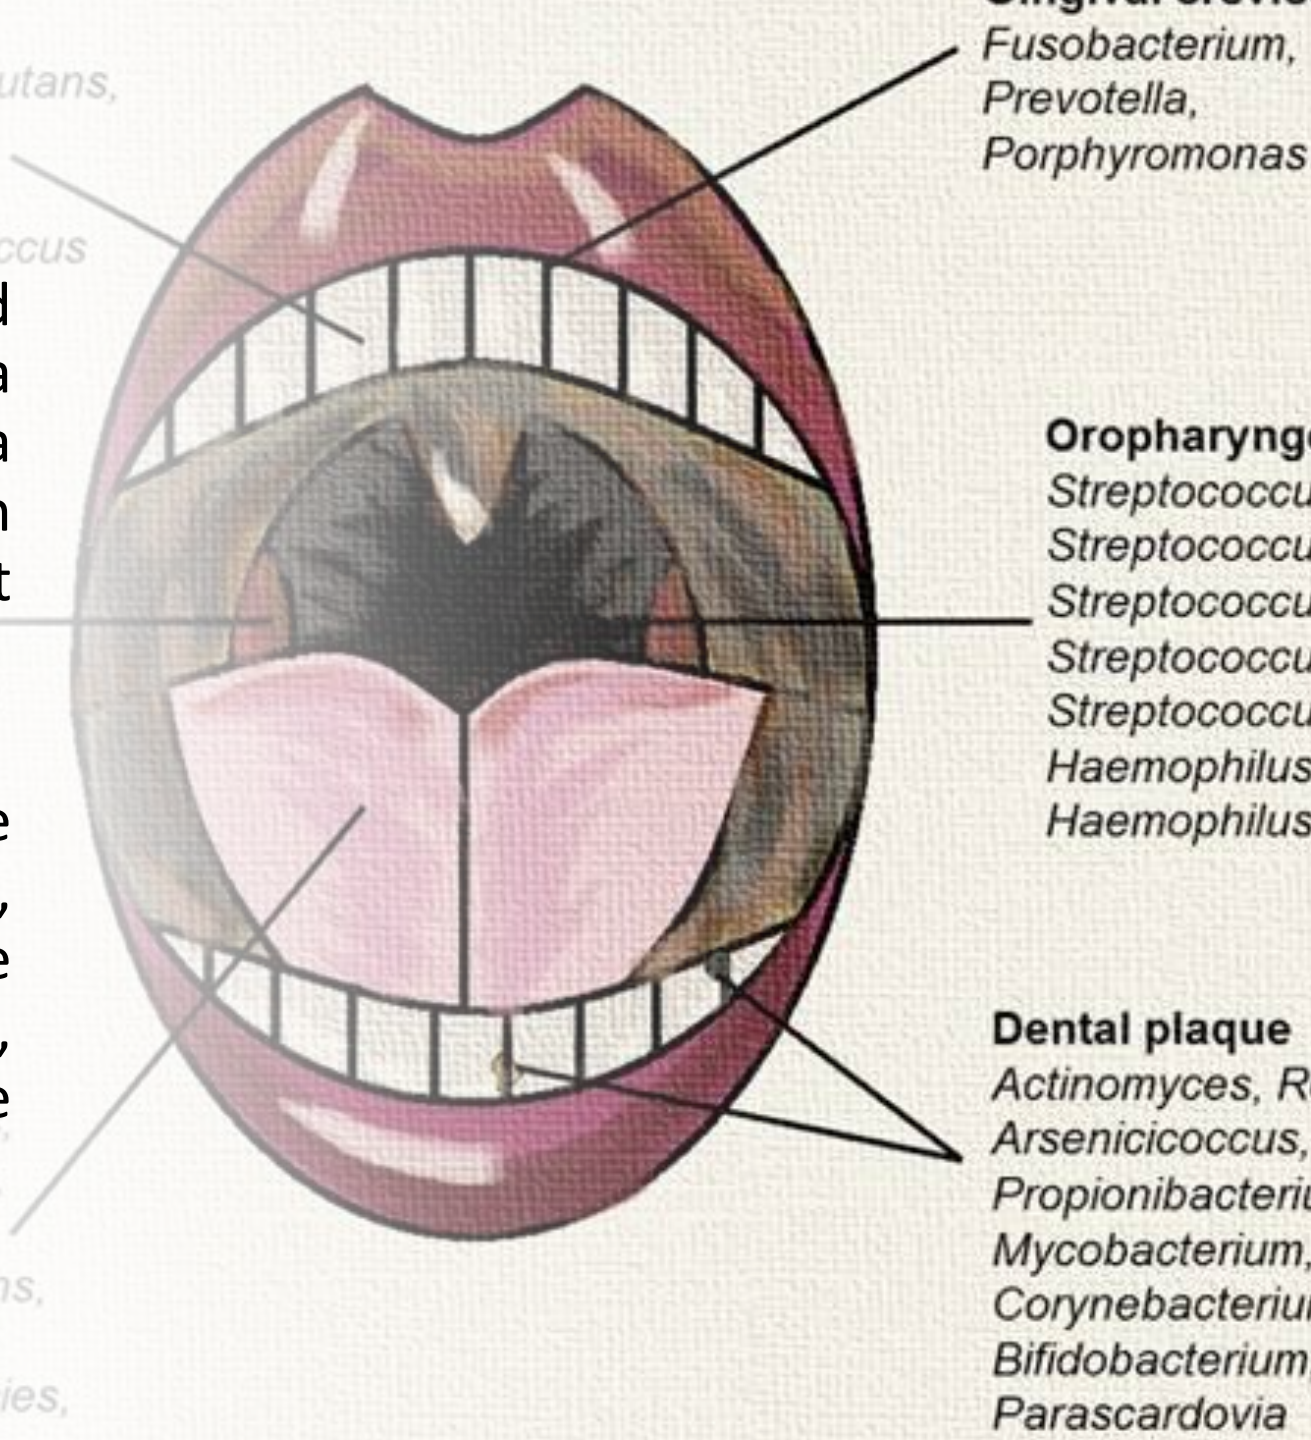
- **Oral Microbiota:**
- The Normal bacterial flora that are placed in the oral cavity is called as Oral Microbiota or Oral Microflora. Both host and bacteria are thought to derive benefit from each other, this the associations is, for the most part, **mutualistic.**

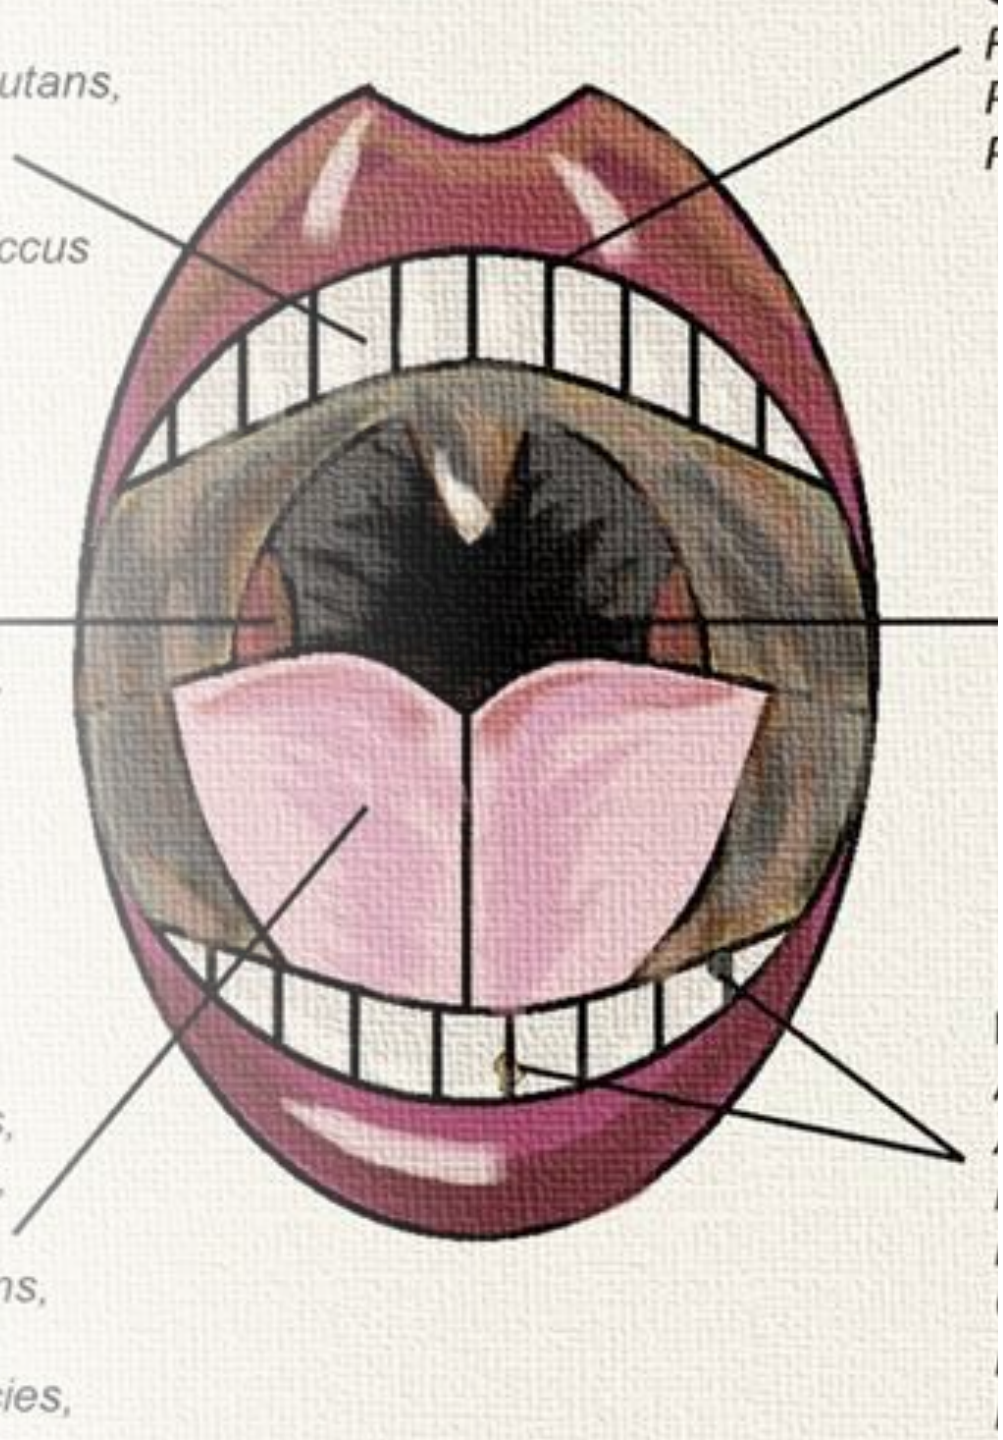
- This resident microflora does not have merely a passive relationship with its host, but contributes directly and indirectly to the normal development of the physiology, nutrition and defense systems of the organism.



- The microbial colonization of all environmentally accessible surfaces of the body (both external and internal) begins at birth.

- Such surfaces are exposed to a wide range of microorganisms derived from the environment and from other persons For example, staphylococci and micrococci predominate on the skin surface.

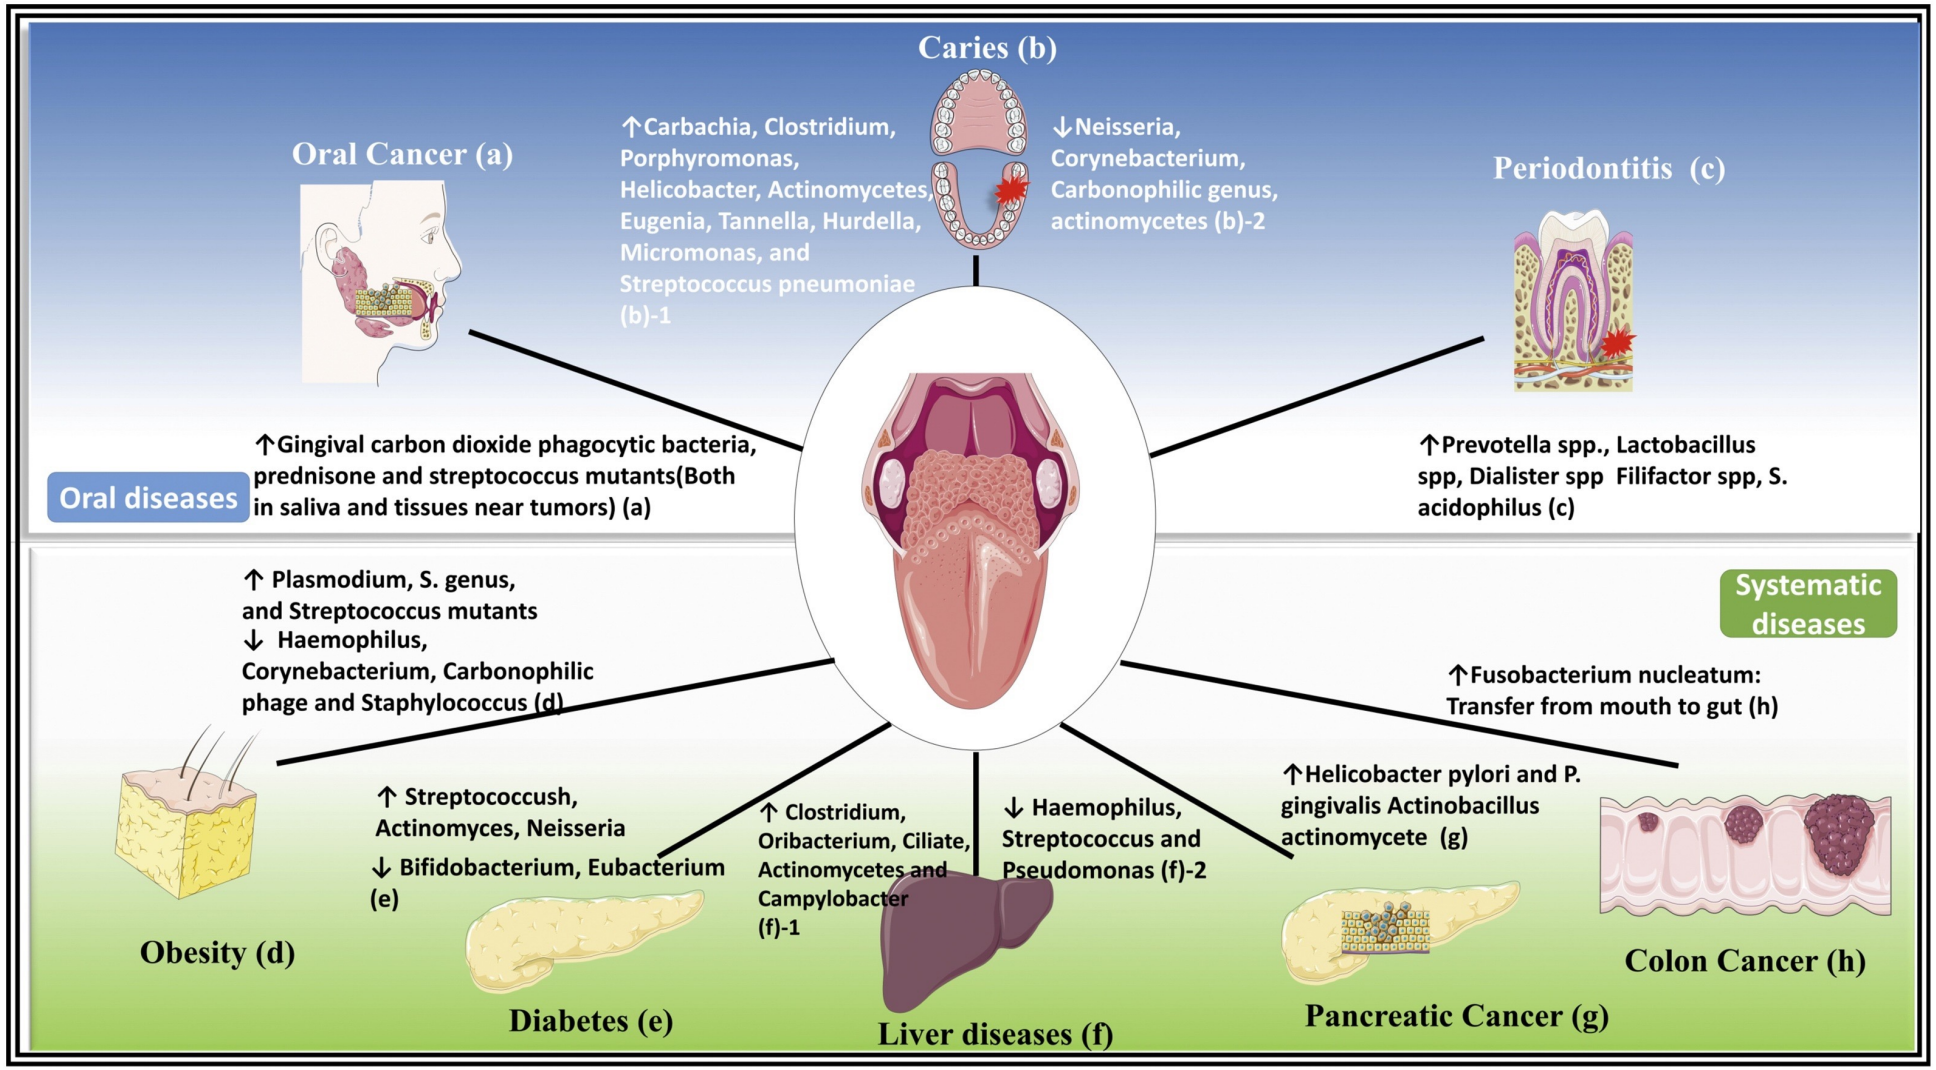
- Similarly, over 700 types of microorganism found in the mouth are able to colonize the gastrointestinal tract, despite the continual passage of these microbes through the gut.



The relationship between the normal flora and the host can be broken down in the mouth and the disease may occur. This usually due to:

- 1-Major biological changes of the mouth from exogenous sources (e.g. Antibiotic treatment) or **Endogenous changes** (Alterations in the host defenses) which affect the natural stability of the microflora.
- 2- -The presence of microorganisms at the sites not normally accessible to them as normal flora.

- As sequence of mouth-normal flora relationship disorder, Localized episodes of disease in the mouth caused by its oral microflora. The commonest clinical aspect of such imbalances are dental caries and periodontal diseases.



- **Dental caries:** is a decay of enamel or root surfaces by acid produced primarily from the metabolism of fermentable carbohydrates of the bacterial diet that are colonizing the tooth surface (dental plaque).

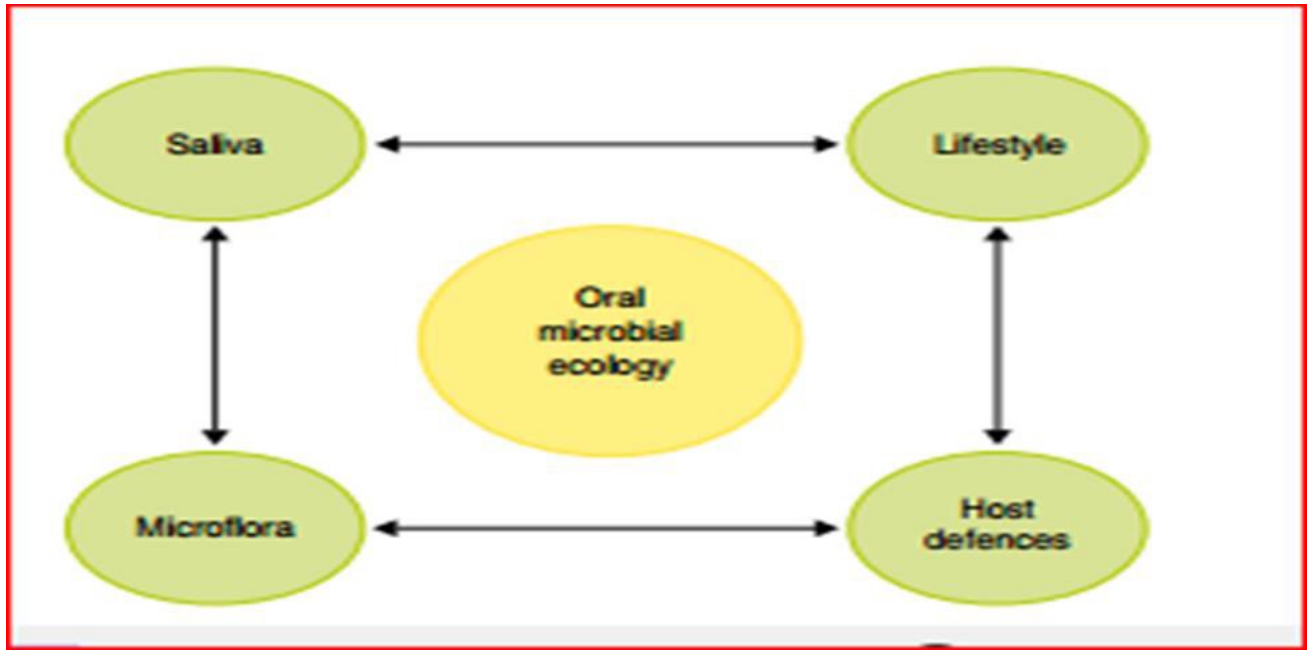
- Dental plaque is also associated with the etiology of periodontal diseases which causes an inappropriate inflammatory response to an increased microbial load (due to plaque accumulation) around the gingivae, resulting in damage to the supporting tissues of the teeth.

MICROBIAL ECOLOGY

Most diseases of the mouth have a polymicrobial (multiple species) etiology. The ability of bacteria to cause disease depends on the outcome of various interactions among the microbes themselves, and between these microorganisms and the host.

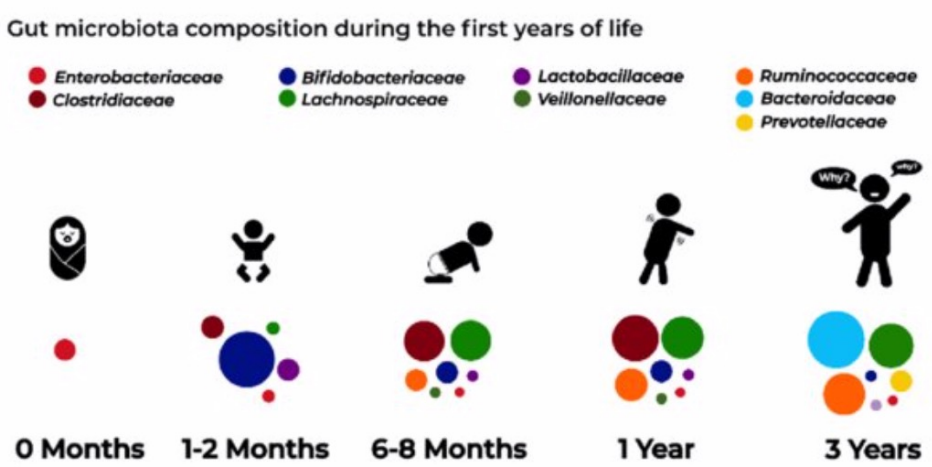
The the microbial ecology of the oral cavity is influenced by:

- 1- Flow rate and properties of saliva
- 2- The life-style of an individual (in particular, the presence of a tobacco habit, the nature of the diet, and exposure to medication)
- 3- The integrity of the host defenses.
- 4- Oral microflora



The mouth as a microbial habitat

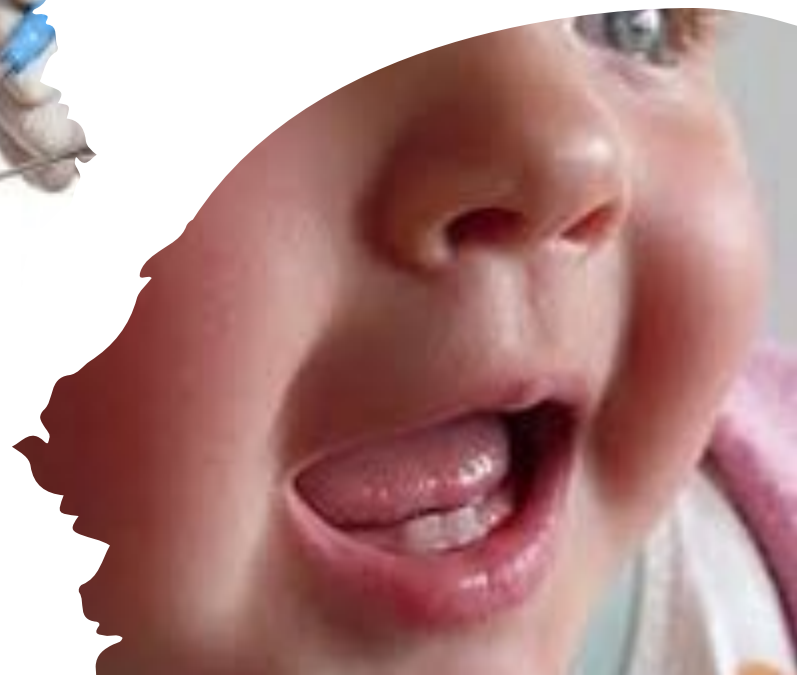
The properties of the mouth as a microbial habitat are dynamic, and will change during the life of an individual. During the first few months of life the mouth consists only of mucosal surfaces for microbial colonization. The eruption of teeth provides a unique, hard non-shedding surface which enables much larger masses of microorganisms (dental plaque) to accumulate as biofilms. When the Gingival crevicular fluid (GCF) is produced, it can provide additional nutrients for subgingival microorganisms.



The ecology of the mouth will change over time due to the eruption or extraction of teeth, the insertion of orthodontic bands or dentures, and any dental treatment including scaling and restorations.

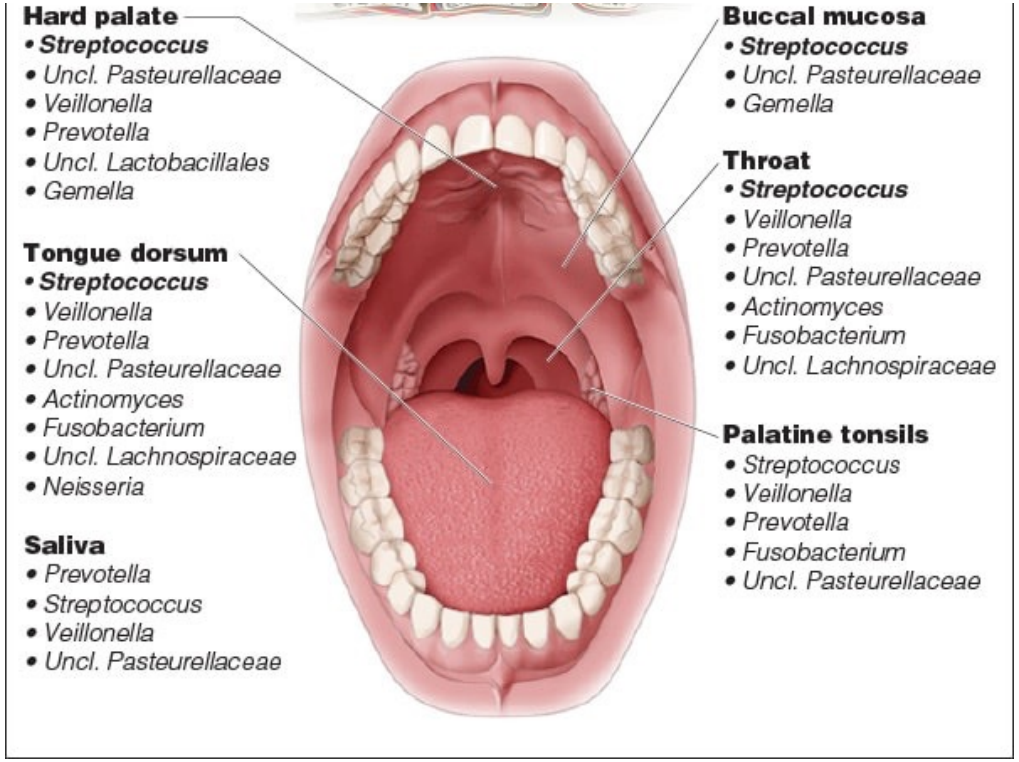
Transient fluctuations in the stability of the oral ecosystem may be induced by the frequency and type of food ingested, variations in saliva flow, and courses of antibiotic therapy.

Four features that help to make the oral cavity distinct from other areas of the body are: **specialized mucosal surfaces, teeth, saliva and gingival crevicular fluid.**

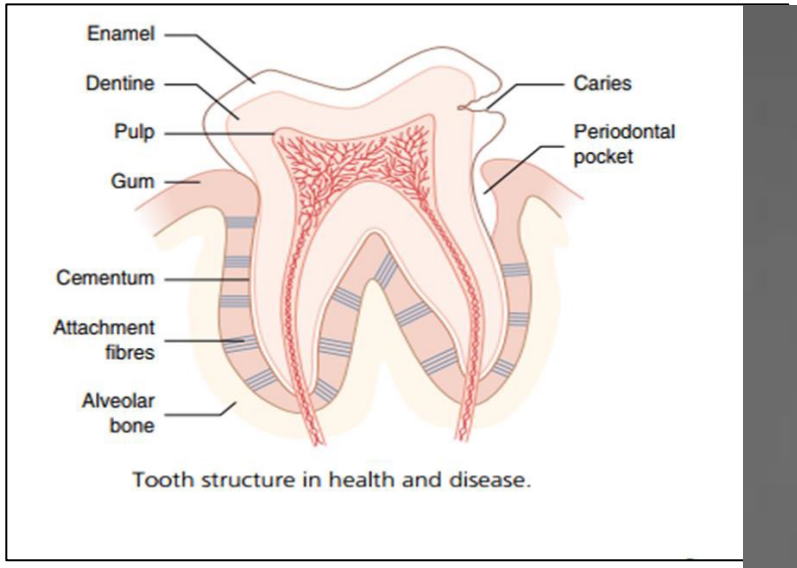


- **Mucosal surfaces**

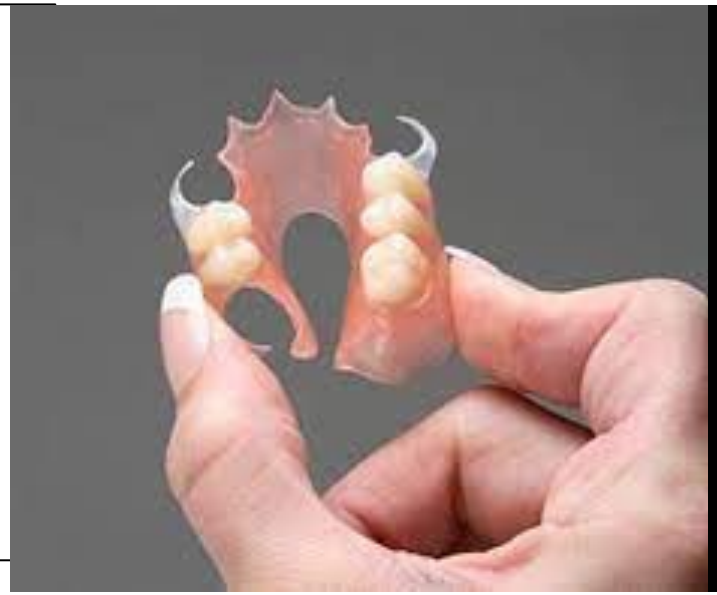
The mouth is similar to other ecosystems in the digestive tract in having mucosal surfaces for microbial colonization. The microbial load is relatively low on such surfaces due to desquamation. The papillary structure of the tongue dorsum provides refuge for many microorganisms which would otherwise be removed by mastication and the flow of saliva. Such sites on the tongue can also have a low redox potential which enable obligately anaerobic bacteria to grow and act as a reservoir for some of the Gram negative anaerobes that are implicated in the etiology of periodontal diseases and are responsible for malodor. The mouth also contains keratinized and non-keratinized stratified squamous epithelium which may influence the oral distribution of some microorganisms.



- **Teeth :**Teeth (and dentures) allow the accumulation of large masses of microorganisms and their extracellular products, termed dental plaque. In disease, there is a shift in the composition of the plaque microflora away from the species that predominate in health. With ageing, recession of the gingival tissues can expose cementum to microbial colonization and disease.



Tooth structure in health and disease.



Teeth do not provide a uniform habitat but possess several distinct surfaces. These surfaces are optimal for colonization and growth by different populations of microorganism.

1- The stagnant areas between adjacent teeth **(approximal)** and the gingival crevice afford most protection to colonizing microorganisms in the mouth . Both sites are also anaerobic and, in addition, the gingival crevice region is bathed with the nutritionally-rich gingival crevicular fluid (GCF), particularly during inflammation.

2- Smooth surfaces are more exposed to the environment and can only be colonized by a limited number of bacterial species.

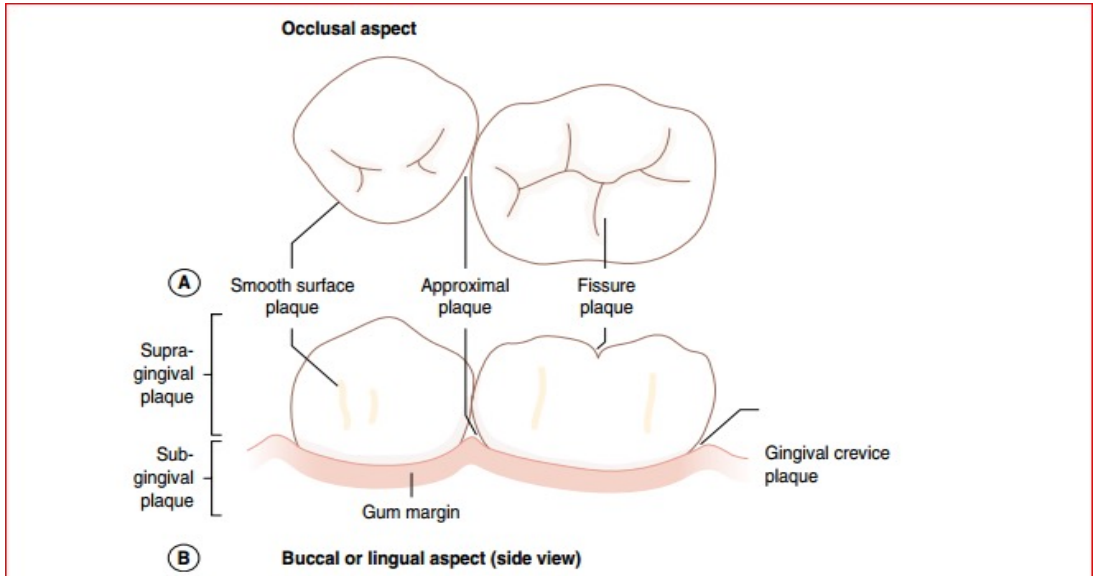


Diagram illustrating the different surfaces of a tooth, and the terminology used to describe dental plaque sampling sites.

3- Pits and fissures of the biting (occlusal) surfaces of the teeth also offer protection from oral removal forces such as saliva flow, and can contain impacted food debris. Environmental conditions on the tooth also vary in health and disease . For example, as caries progresses, the advancing front of the lesion penetrates the dentine.

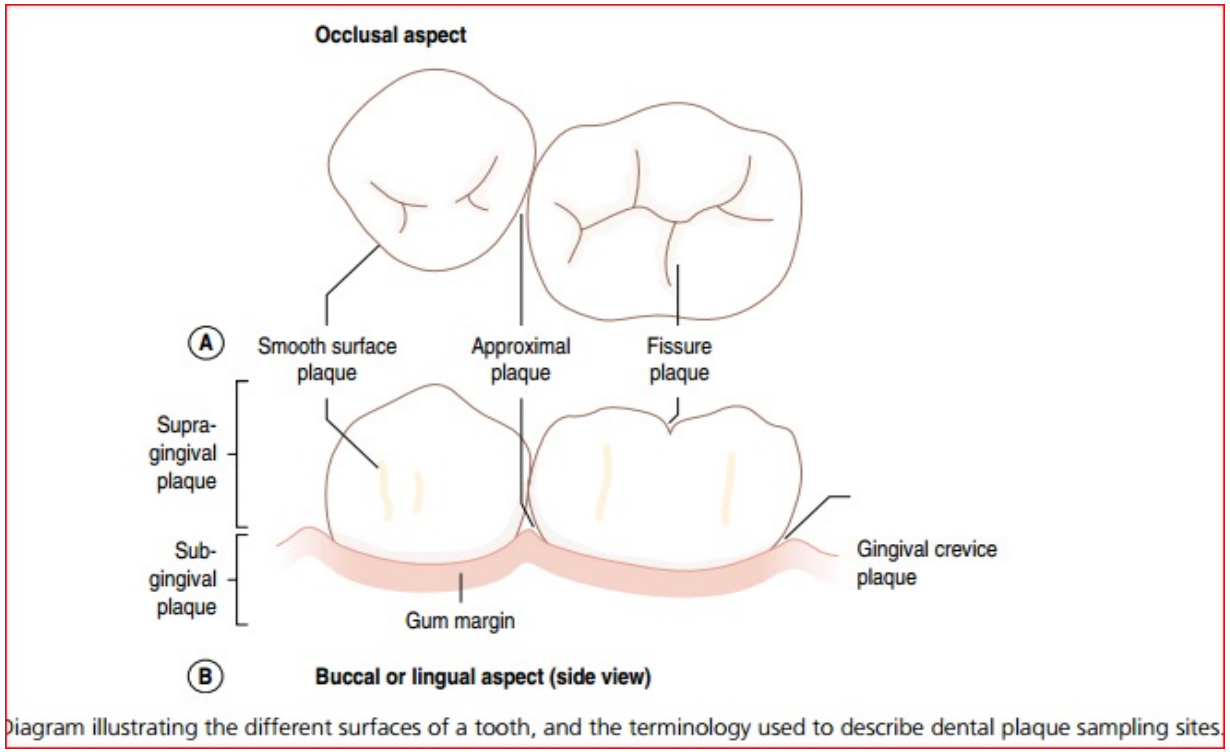

Diagram illustrating the different surfaces of a tooth, and the terminology used to describe dental plaque sampling sites.

- The nutritional sources can be changed and local conditions may become acidic and more anaerobic due to the accumulation of bacterial metabolism products. Similarly, in disease, the gingival crevice is developed into a periodontal pocket and the production of GCF is increased. These new environments will select the microbial community most adapted to the prevailing conditions. there for change in the local environment possibly resulting in a shift in the composition and metabolism of the microflora.

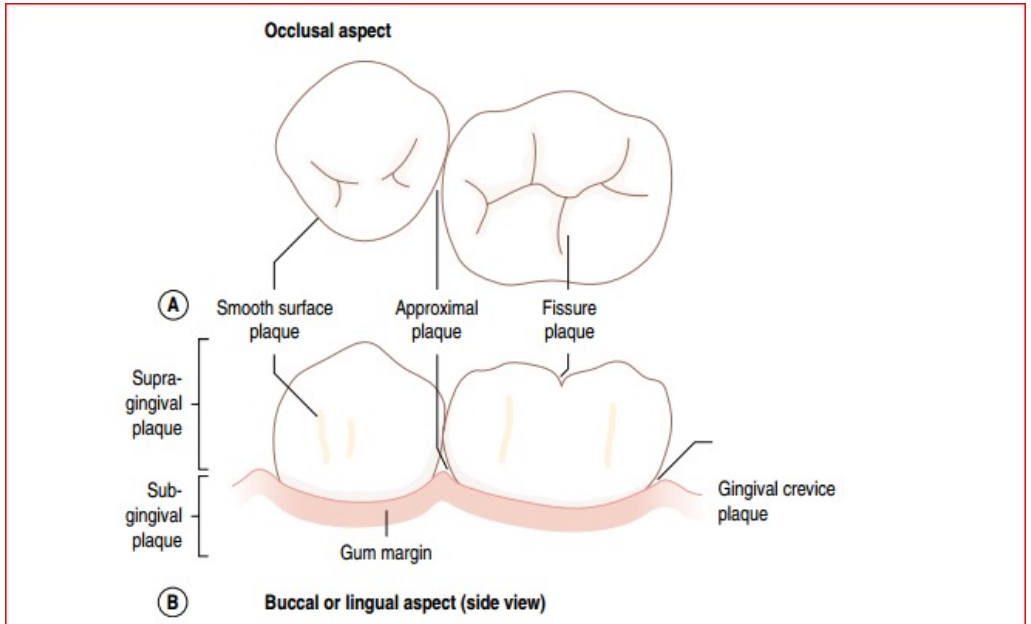

Diagram illustrating the different surfaces of a tooth, and the terminology used to describe dental plaque sampling sites.

- **Saliva**

The mouth is kept moist and lubricated by saliva which flows to form a thin film (approximately 0.1mm deep) over all the internal surfaces of the oral cavity. Saliva plays the buffering role and Bicarbonate is the major buffering system in saliva. Phosphates, peptides and proteins are also involved. The mean pH of saliva is between pH 6.75 and 7.25, the pH and buffering capacity will vary with the flow rate. The slowest flow of saliva occurring during sleep.

The major organic constituents of saliva are **proteins and glycoproteins**, such as **mucin**, and they influence the oral microflora by:

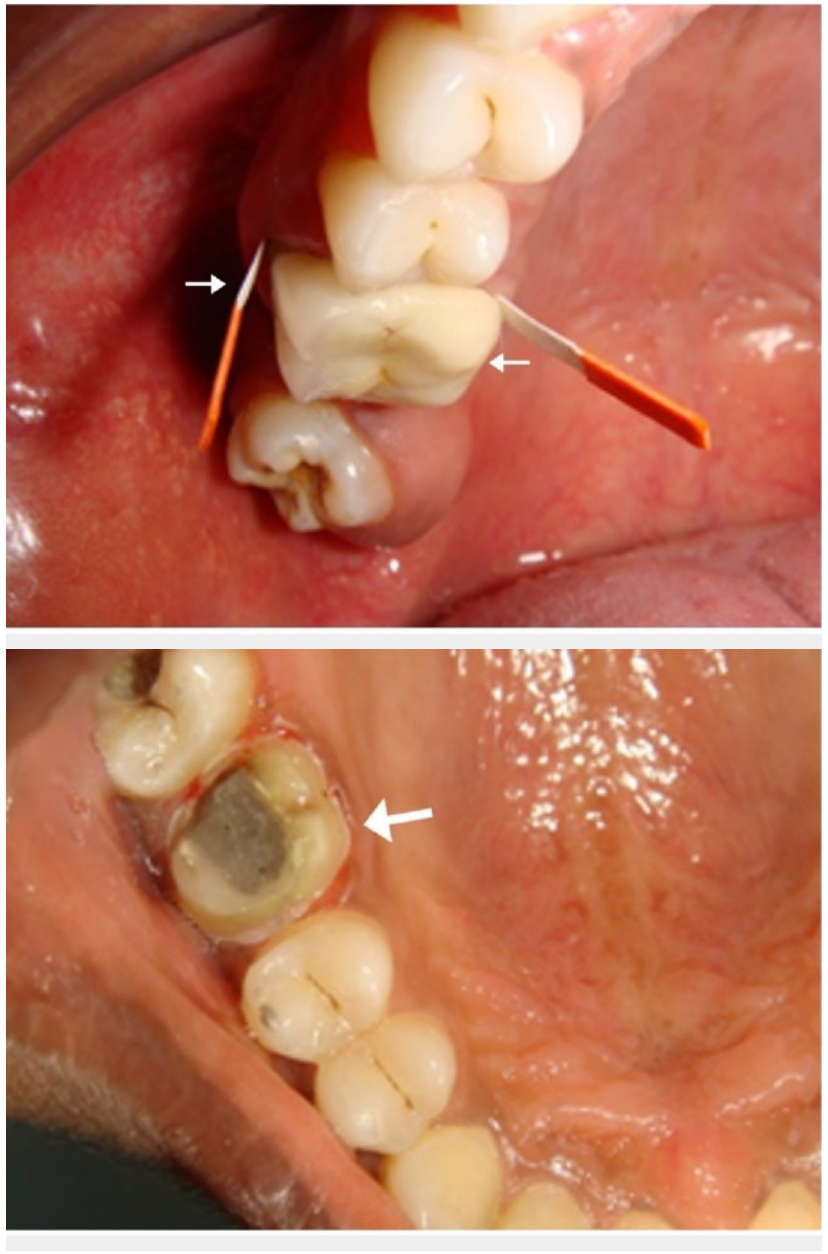
- Adsorbing to the tooth surface to form a conditioning film (the acquired pellicle), when microorganisms are able to attach
- Acting as primary sources of nutrients (carbohydrates and proteins) for the resident microflora,
- Aggregating exogenous microorganisms, thereby facilitating their clearance from the mouth by swallowing,
- Inhibiting the growth of some exogenous microorganisms

- Other **nitrogenous** compounds provided by saliva include urea and numerous amino acids. The concentration of free carbohydrates is low in saliva, and most oral bacteria produce glycosidases to degrade the side-chains of host glycoproteins. The metabolism of amino acids, peptides, proteins and urea can lead to the net production of alkalines, which contributes the acids production that resulted from fermentable carbohydrates.

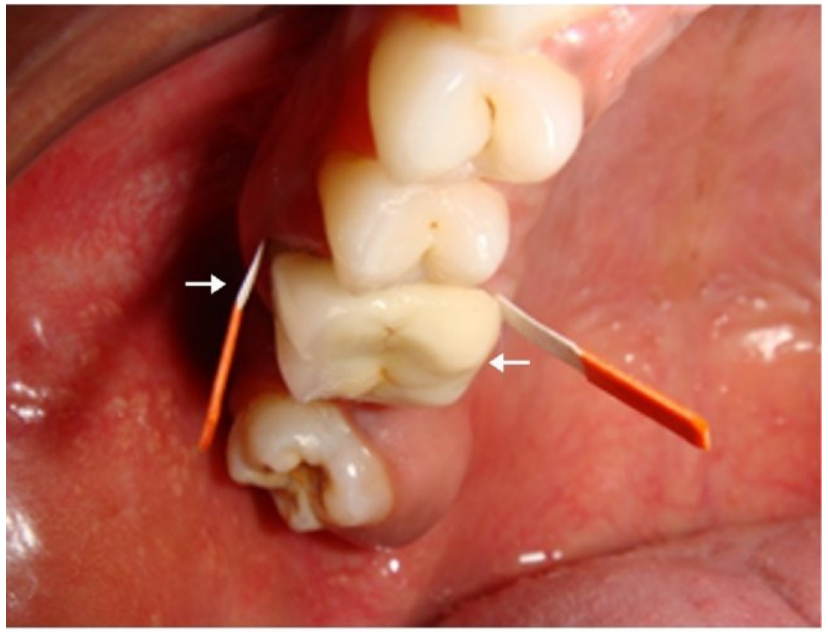
- **Antimicrobial factors**, including lysozyme, lactoferrin, and the sialo peroxidase system, are present in saliva and play a key role in controlling bacterial and fungal colonization of the mouth. Antibodies have been detected, with **secretory IgA (sIgA) being the predominant class of immunoglobulin.**
- **IgG and IgM are also present but in lower concentrations**. A range of peptides with antimicrobial activity, including histidine-rich polypeptides (histatins), cystatins and defensins are also present in saliva.

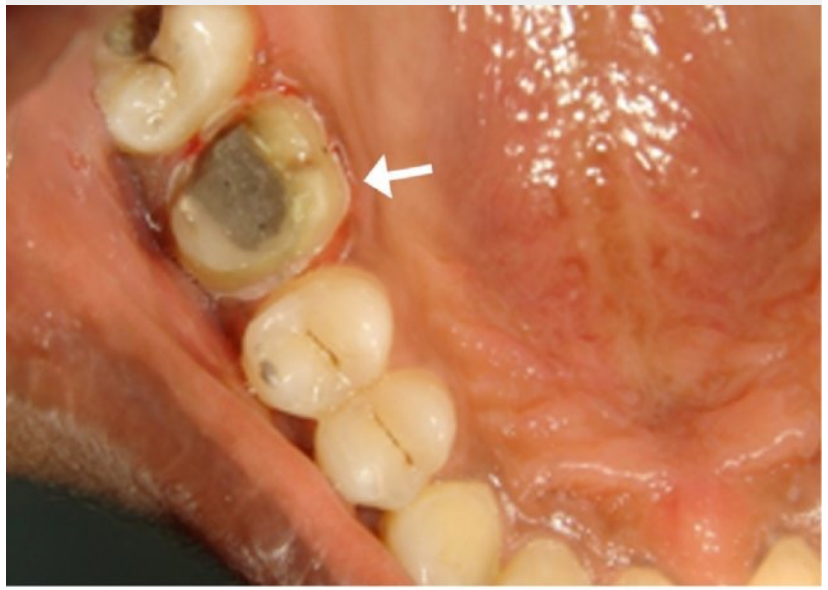
Gingival crevicular fluid (GCF)

- Serum components can reach the mouth by the flow of a serum-like fluid through the junctional epithelium of the gingiva. The flow of **gingival crevicular fluid (GCF)** is relatively slow at healthy sites, increases in gingivitis and in advanced periodontal diseases, as part of the inflammatory response to the accumulation of plaque around the gingival margin.
- GCF can influence the microbial ecology of the site in a number of ways.* Its flow will remove non-adherent microbial cells, and *introduce components of the host defenses, especially IgG and neutrophils.



- GCF contains components of the host defenses. regulating the microflora of the gingival crevice in health and disease. **IgM and IgA are also present, as acomplement.** GCF contains leukocytes, of which 95% are neutrophils(can phagocytose bacteria within the crevice), the remainder being lymphocytes and monocytes





Factors Affecting Oral Microbial Growth

- ***Temperature***

The human mouth temperature is (35–36°C) provides stable conditions, suitable for the growth of microorganisms. Periodontal pockets with inflammation have a higher temperature (up to 39°C) compared with healthy sites. Small increasing in temperature can significantly alter bacterial gene expression, and possibly the competitiveness of individual species. A rise in temperature down-regulates the expression (gene downregulation is the process by **which a cell decreases the quantity of a gene expression product)** of some of the major proteases and fimbriae proteins in the periodontal pathogen, *Porphyromonas gingivalis*, and up-regulates (gene expression up-regulation is the process by which **a cell increases the quantity of a gene expression product)** synthesis of superoxide dismutase, which is involved in the neutralization of toxic oxygen metabolites.

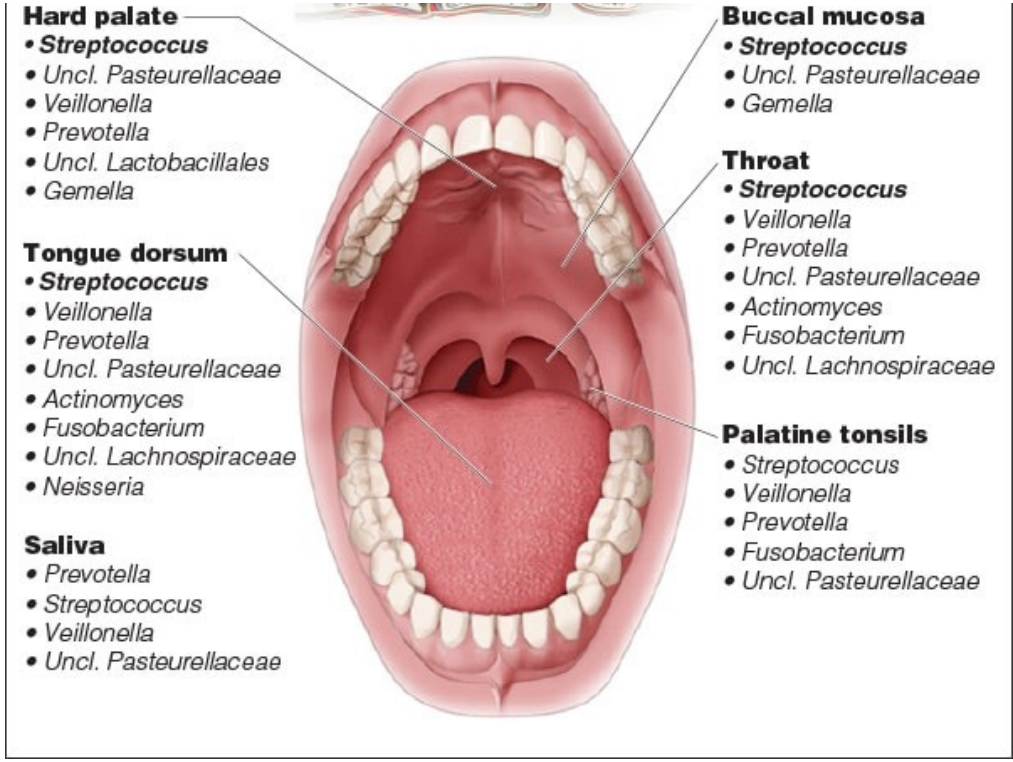
$$O_2^{\circ-} + 2H \xrightarrow{\text{dismutase}} O_2 + H_2O_2$$

- **Oxygen tension :**

Oxygen concentrations are very at different locations in the oral cavity.

As may be expected, the dorsum of the tongue and the buccal and palatal mucosa are in an essentially aerobic environment.

The oxygen tension inside a periodontal pocket is very low, with the species having a tendency to become reduced rather than oxidized, explaining the survival of obligate anaerobe. Therefore obligate aerobic organisms (which require oxygen) cannot survive, whereas obligate anaerobic organisms (which cannot tolerate the presence of oxygen) are able to thrive.



- **pH :**Shifts in the proportions of bacteria within dental plaque can occur following fluctuations in environmental pH .
- After sugar consumption, the pH in plaque can fall rapidly to below pH 5.0 by the production of lactic acid, the bacteria in plaque will be exposed to challenge of low pH .
- In many of the predominant plaque, bacteria that are associated with healthy sites can tolerate brief conditions of low pH, but are inhibited or killed by frequent or long exposures to acidic conditions. This can enhanced growth of, or colonization by, **acid-tolerant species, mutans streptococci and Lactobacillus** .
- In contrast, the pH of the gingival crevice can become alkaline during the host inflammatory response in periodontal disease, probably as a result of bacterial metabolism, e.g. ammonia production from urea. The pH of the healthy gingival crevice is 6.90, and rises to between pH 7.2 and 7.4 during disease. High PH can alter the pattern of gene expression in subgingival bacteria

- **Nutrients:**
- **(i) Endogenous nutrients** The persistence and diversity of the resident oral microflora is due primarily to the metabolism of the endogenous nutrients provided by the host, rather than by exogenous factors in the diet.

Saliva, which contains amino acids, peptides, proteins and glycoproteins vitamins and gases.

Gingival crevice is supplied with GCF(nutrients, such as albumin and other host proteins and glycoproteins, including haeme containing molecules) .

- **(ii) Exogenous** (dietary) nutrients ,fermentable carbohydrates are the only class of compound that markedly influence the ecology of the mouth. broken down to acids.

The levels of acid-tolerating species, especially mutans streptococci and lactobacilli, increase while the growth of acid-sensitive species (*Streptococcus sanguinis* and *S. gordonii*) is inhibited or decreased. This predispose a site to dental caries. Dairy products (milk, cheese) have some influence on the ecology of the mouth.

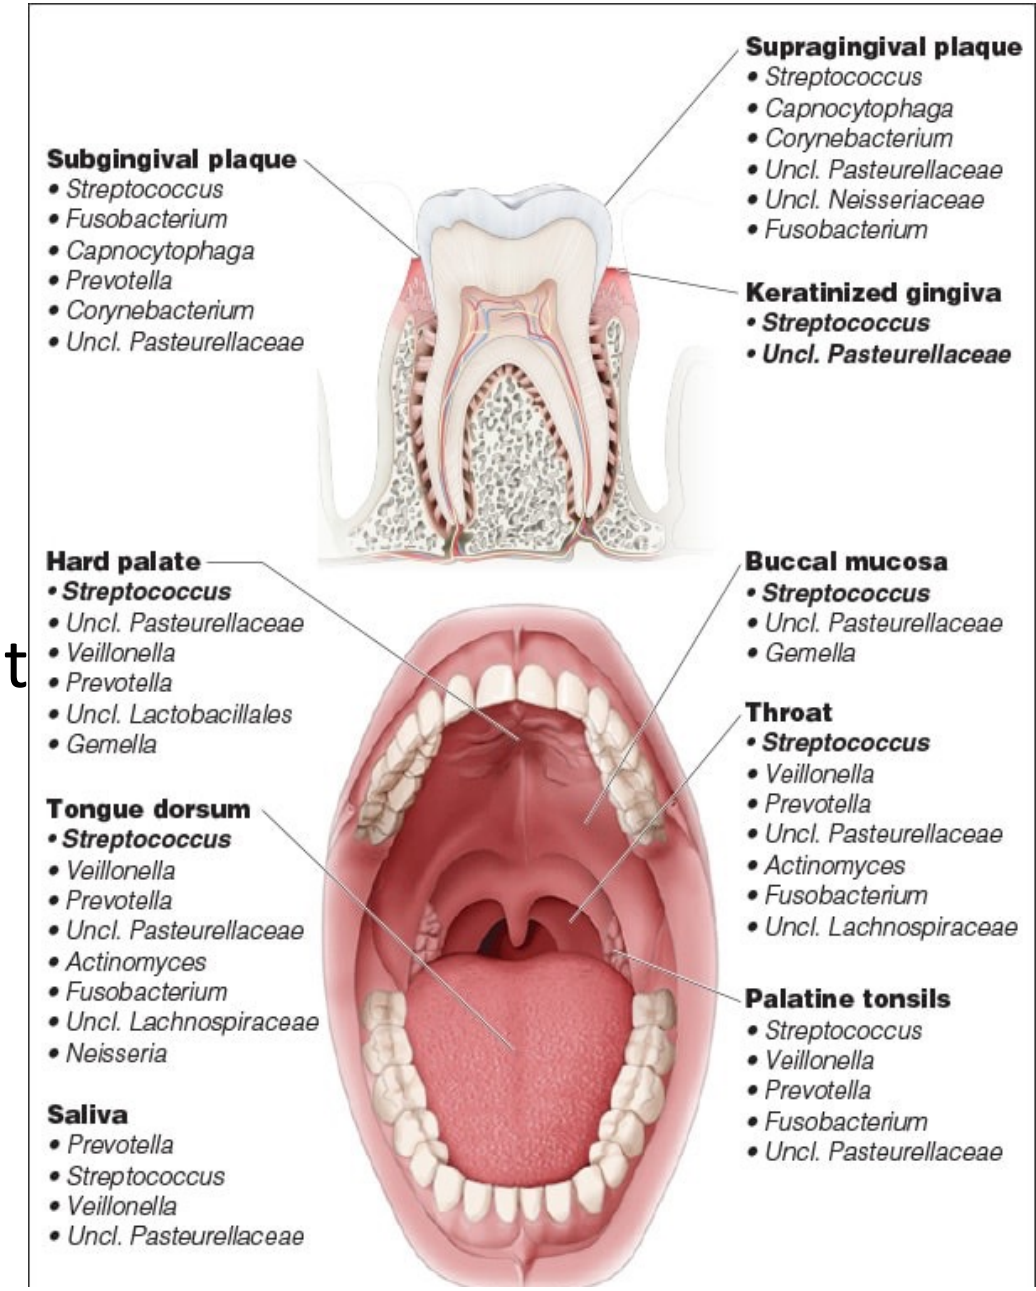
- **Host defenses**
- Mucosa (and enamel) a physical barrier to prevent penetration by microorganisms or antigens
- **(i) Innate immunity**: Chewing and the natural flow of saliva (or GCF in the gingival crevice) will remove microorganisms not firmly attached to an oral surface, and their physical removal by **swallowing** is an important defense mechanism., desquamation ensures that the bacterial load on most mucosal surfaces is light .

- **Mucins** agglutinate oral bacteria, interact with exogenous pathogens such as *Staphylococcus aureus* and *Pseudomonas aeruginosa*, as well as viruses including influenza virus.
- **Lysozyme** aggregate both Gram positive bacteria (including streptococci) and Gram negative periodontal pathogens. lyse bacteria by hydrolyzing peptidoglycan.
- **Chitinase** attacking yeast cell walls.
- **lactoferrin** bactericidal to a range of Gram positive and Gram negative bacteria and anti-inflammatory
- **Defensins** are a family of antibacterial peptides with a broad spectrum of antibacterial, antifungal and antiviral (including HIV) activity.
- **Cathelicidin** antimicrobial peptide that is secreted by epithelial cell.

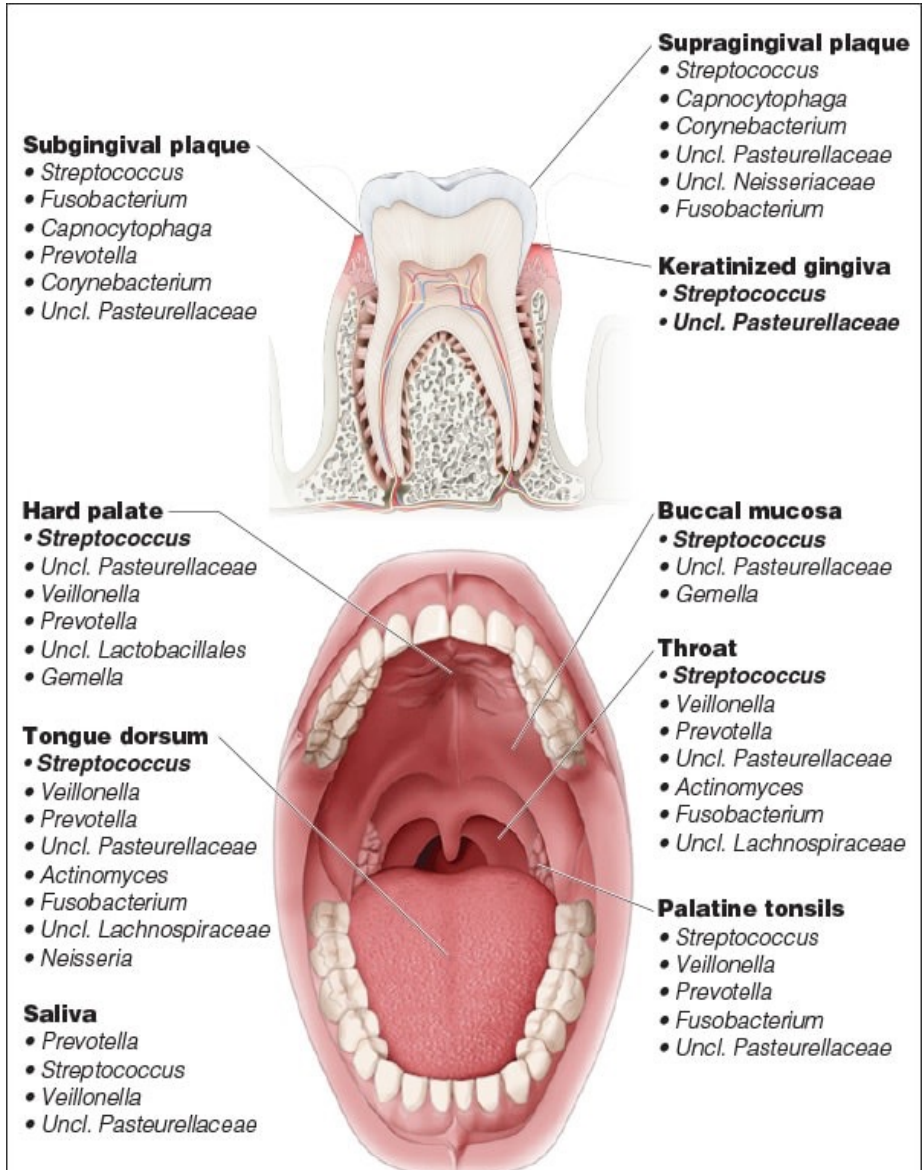
- **(ii) Adaptive immunity**: Components of the specific host defences (intraepithelial lymphocytes and Langerhans cells (tissue macrophage), immunoglobulins IgG and IgA) are found on and within the mucosa. where they act as a barrier to penetrating antigens. The predominant immunoglobulin in the healthy mouth is secretory IgA (sIgA), which is produced by plasma cells in the salivary gland. sIgA can agglutinate oral bacteria, modulate enzyme activity, and inhibit the adherence of bacteria to the buccal epithelium and to enamel. sIgA is usually considered to be a first line of defenses compared with other classes of immunoglobulin.

- **The resident oral microflora**
- **Gram positive** bacteria are commonly distributed on most surfaces of the mouth. The predominant genera are Streptococcus and Actinomyces; representative species are found at healthy sites, although many can also act as opportunistic pathogens. For example, mutans streptococci are implicated in dental caries .

Other Gram positive cocci : *Enterococcus faecalis*

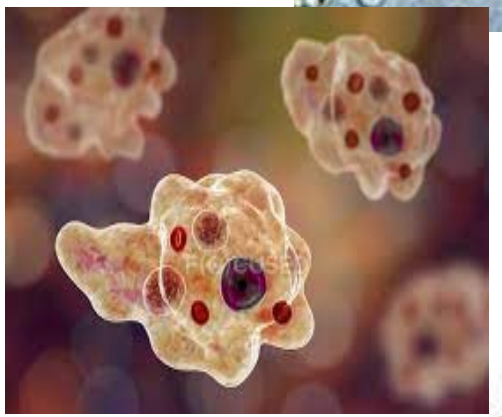


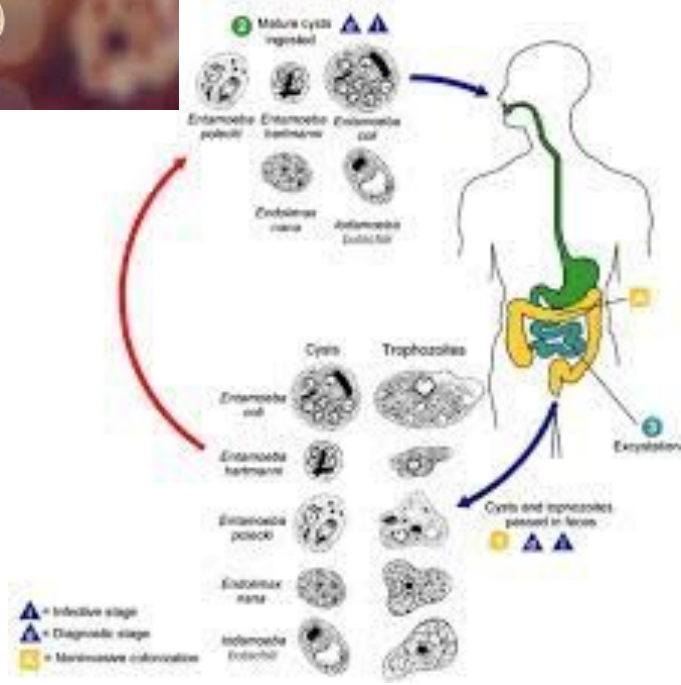
- **Oral Gram negative** bacteria are diverse, and include species that are facultatively and obligately anaerobic, as well as species that are microaerophilic and capnophilic. **Veillonella** are anaerobic Gram negative cocci that play an important role in dental plaque by converting lactate to weaker acids. Most of the anaerobic Gram negative bacilli are found in dental plaque, and have an a saccharolytic metabolism, and depend on proteins and glycoproteins for their nutrition; some common genera include Prevotella and Fusobacterium.



- **GRAM NEGATIVE COCCI:** Neisseria**,**Veillonella

- **Facultatively anaerobic and capnophilic genera**
- *H. parainfluenzae*
- **Obligately anaerobic genera :**Prevotella
- **FUNGI Aspergillus, Candida(*Candida albicans*)**
- **VIRUSES: Cytomegalovirus**
- **PROTOZOA: *Trichomonas tenax, Entamoeba gingivalis***





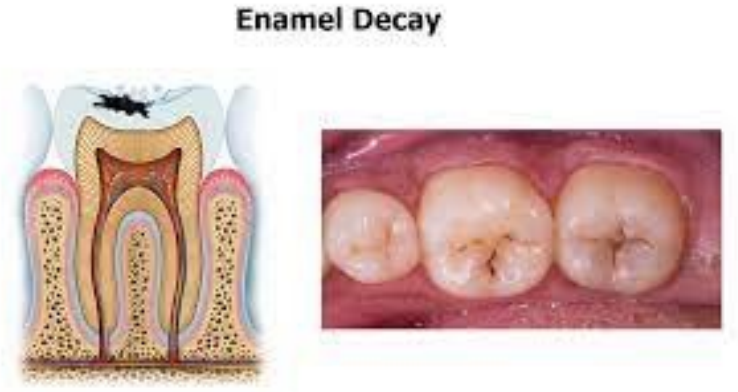
Oral flora changes with age

Time during a lifetime	MAJOR COMPONENTS & CHANGES IN ORAL FLORA
Newborn	Oral cavity sterile. Soon colonised by facultative and aerobic organisms; esp *S. salivarius*
6 months	Flora becomes more complex & includes anaerobic orgs eg. *Veillonella sp. & Fusobacteria*
Tooth eruption	Increase in complexity. *S sanguis, S mutans* and *A viscosus* appear. New habitats include hard surfaces and gingival crevice.
Child to adult	Various anaerobes frequently found inc. Members of the *Bacteroidaceae. Spirochaetes* isolated more frequently
Loss of teeth	Disappearance of *S mutan, S sanguis, spirochaetes* and many anaerobes
Dentures etc	Reappearance of bacteria able to grow on hard surfaces

Dental plaque and Dental Caries

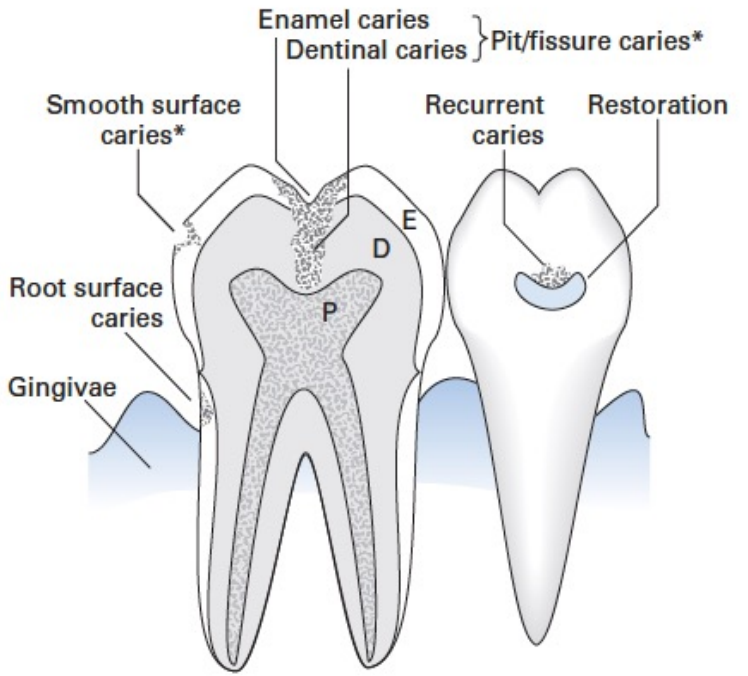
Dental plaque is a biofilm of microorganisms (mostly bacteria, but also fungi) that grows on surfaces within the mouth . It is a sticky colorless deposit at first, but when it forms tartar, it is often brown or pale yellow. It is commonly found between the teeth, on the front of teeth, behind teeth, on chewing surfaces, along the gumline, or below the gumline cervical margins.

- **Dental caries** is a chronic endogenous infection caused by the normal oral commensal flora. The carious lesion is the result of demineralization of enamel (and later of the dentine) by acids produced by plaque microorganisms that metabolize dietary carbohydrates and the cavitation occur . once the surface layer of enamel has been lost the infection progresses to dentine, becoming firstly inflamed and then necrotic.



Classification of dental caries Dental caries can be classified with respect to the site of the lesion

- pit or fissure caries (seen in molars, premolars and the lingual surface of maxillary incisors)
- smooth surface caries (seen mainly on approximal tooth surface just below the contact point)
- root surface caries (seen on cementum or dentine when the root is exposed to the oral environment)
- recurrent caries (associated with an existing restoration)

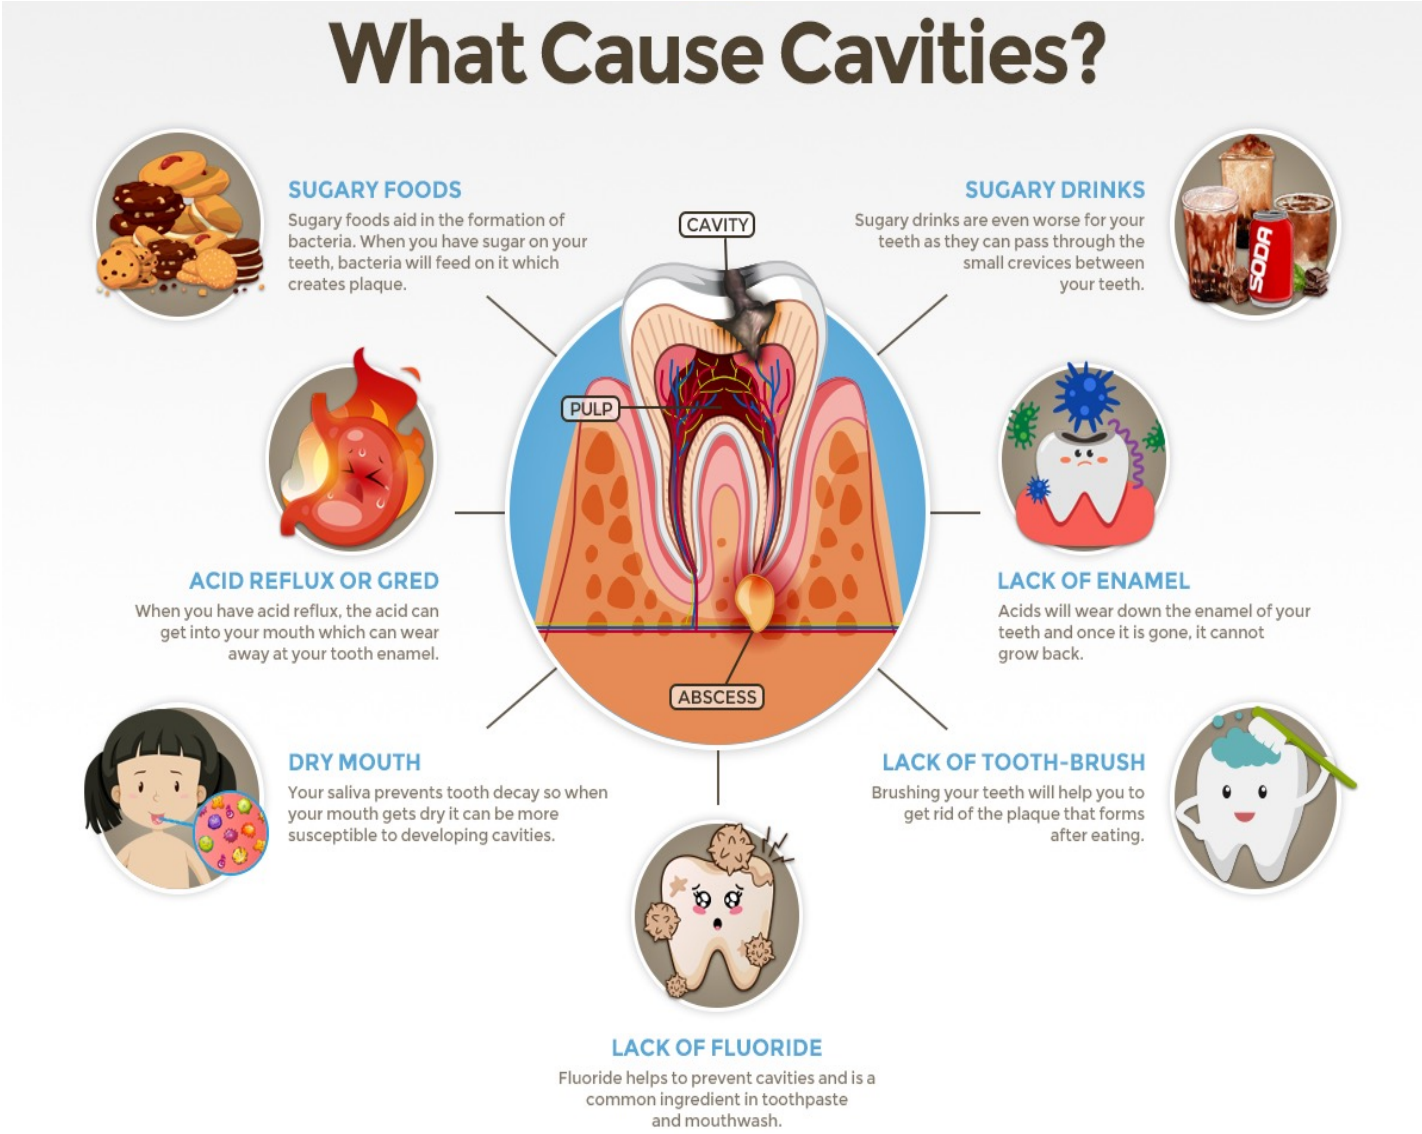


Nomenclature of dental caries. D, dentine; E, enamel; P, pulp.
*Also termed occlusal caries.

Aetiology

The major factors involved in the caries:

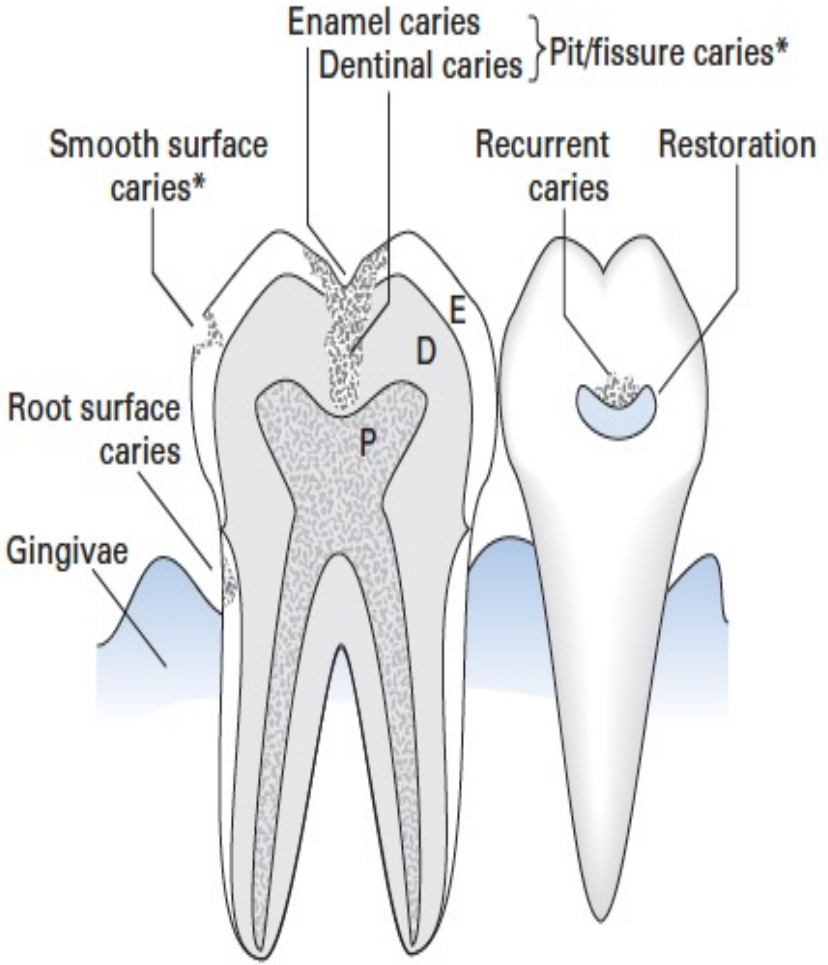
- Host factor (tooth and saliva)
- Diet
- Microorganisms



Host factors

1-Tooth structure

Some areas of the same tooth are much more susceptible to carious attack than others, possibly because of difference in mineral content (especially fluoride).



Nomenclature of dental caries. D, dentine; E, enamel; P, pulp.
*Also termed occlusal caries.

Host factors

2-Flow rate and composition of saliva

-The mechanical washing action of saliva is a very effective mechanism in the removal of food debris and unattached oral microorganisms.

- it has buffering capacity

-it acts as a delivery vehicle for fluoride.

Diet

There is a direct relationship between dental caries and the intake of carbohydrates. The most cariogenic sugar is sucrose. Sucrose is highly soluble and diffuse easily into the dental plaque acting as a substrate for the bacteria to produce extracellular polysaccharides and acids. For example, Cariogenic streptococci produce water-unsoluble **glucan** from sucrose, which **in addition** to facilitating **initial adhesion** of the organism to the tooth surface, it serves as a **nutritional source and matrix** for farther plaque development.

- Other cariogenic carbohydrates are glucose and fructose.

Microbiology

Microorganisms in the form of dental plaque are a precondition for the development of dental caries.

Dental plaque hypothesis

There two hypotheses for dental plaque and caries according to the relationship with microorganisms:

- The specific plaque hypothesis: One or more specific group of bacteria are principally involved in caries (e.g. *mutans* streptococci group).

- Non-specific plaque hypothesis: the disease is caused by heterogenous mixture of non-specific bacteria.

The role of *mutans* streptococci

The species *Streptococcus mutans,* with its serotypes (c, e, f and s), and *Streptococcus sobrinus,* with serotypes d and g, are the most commonly found in humans.

The evidences of their role in dental caries are:

- Correlation between mutans streptococci counts in saliva and plaque with prevalence and incidence of caries.
- production of extracellular polysaccharides from sucrose and intracellular polysaccharides as glycogen (acts as a food store for use when dietary carbohydrate is low). .
- Ability to produce and maintain microbial growth (biofilm formation) to continue acid production.
- Rapid metabolism of sugars to lactic and other organic acids.
- Ability to attain the critical PH for enamel demineralization more rapidly than other common plaque bacteria.

The role of lactobacilli

lactobacilli has impotent role in dental caries. because of:

- Their high numbers in most carious lesions affecting enamel.
- The positive correlation between their number in plaque and saliva, and caries activity.
- Their ability to grow in low-pH environments and to produce lactic acid.
- Their ability to produce extracellular and intracellular polysaccharides.

It is so important to mention that lactobacilli are rarely isolated from plaques before the development of caries. It is believed that they are involved more in the progression of the deep enamel lesion.

- **The role of *Actinomyces spp.***

Actinomyces spp. are associated with development of root surface caries.

- **The role Veillonella**

Veillonella is gram-negative anaerobic coccus that is present in significant numbers in most supragingival plaque samples.

Plaque metabolism and dental caries

Oral bacteria have developed a number of regulatory mechanisms, which act at three pathways:

- 1. transport of sugar into the organisms
- 2. the glycolytic pathway.
- 3. conversion of pyruvate into metabolic end products.

1. transport of sugar into the organisms

The bacterial metabolism products are responsible for enamel demineralization. The process begins when dietary sugar is broken down by bacterial extracellular enzymes such as glucosyl and fructosyl transferases, with the release for glucose and fructose, respectively. These monosaccharides are then converted into polysaccharides glucans and fructans, respectively.

Glucose $\xrightarrow{\text{Glucosyl transferases}}$ Glucans

Fructose $\xrightarrow{\text{Fructosyl transferases}}$ Fructans

- Glucans are mostly used as a major bacterial food source
- Fructans contribute to the plaque matrix while facilitating the adhesion and aggregation of plaque bacteria and serving as a ready, extracellular food source.

2. the glycolytic pathway.

- During glycolysis, glucose is degraded immediately by bacteria via the glycolytic pathway with production of two bacterial pyruvate molecules from each molecule of glucose (Pyruvate is the conjugated base of pyruvic acid).

3. conversion of pyruvate into metabolic end products.

- The pyruvate can degraded farther into other chemical molecules.
- under low sugar condition, pyruvate is converted into ethanol, acetate and formate.
- in high sugar level, pyruvate is converted into lactate molecules and then lactic acid.

Different species produce acids at different rate and very in their ability to survive under such conditions. the mutens streptococci bacteria reduce the plaque PH to low levels creating hostile conditions for other plaque bacteria.

Microbiology of root surface caries

- Approximately 60% of individuals in the West aged 60 yeas or older now have root caries. This has arisen mainly because of the reduction in enamel caries and the consequential retention of teeth later into life, accompanied by gingival recession. The root soft cemental surface is highly susceptible to microbial colonization, due to its irregular and rough surfaces.

Prevention of dental caries

The major approaches to prevention of caries are:

- **Sugar substitutes**: stopping or reducing between-meal consumption of carbohydrates or substituting non-cariogenic artificial sweeteners.

- **Fluorides**: making the tooth structure less soluble to acid attack by using fluorides rich products.

- **Sealants**: to protect susceptible areas of the tooth (e.g. pit and fissures) that cannot easily be kept plaque-free by routine oral hygiene measures.

- **Reducing cariogenic flora by Probiotics nutrition:** replacement of cariogenic bacteria by organisms with low or no cariogenic potential.

Enteric Gram-Negative Rods (Enterobacteriaceae)

Dr Mohammed R. Mohaisen

Enteric Gram-Negative Rods (Enterobacteriaceae)

INTRODUCTION

The Enterobacteriaceae are a largest, most heterogeneous collection of medically important gram-negative rods, 48 genera, whose natural habitat is the intestinal tract of humans and animals.

The family includes many genera (*Escherichia, Shigella, Salmonella, Enterobacter, Klebsiella, Serratia, Proteus,* and others).

- *Escherichia coli,* are part of the normal flora and incidentally cause disease

- Salmonellae and shigellae, are regularly pathogenic for humans.

The Enterobacteriaceae are facultative anaerobes or aerobes, ferment a wide range of carbohydrates, possess a **complex antigenic structure**, and produce a variety of toxins and other virulence factors.

Enterobacteriaceae or it could be named enteric gram-negative rods (enteric bacteria), or (coliforms).

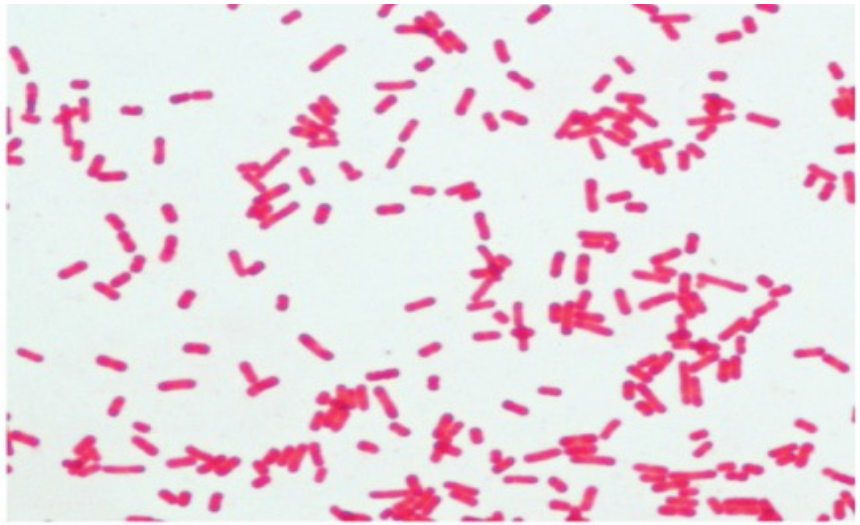
- There are four major features:

-The Enterobacteriaceae are short gram-negative rods (Figure1).

-Typical morphology is seen in growth on solid media in vitro,

- morphology is highly variable in clinical specimens.

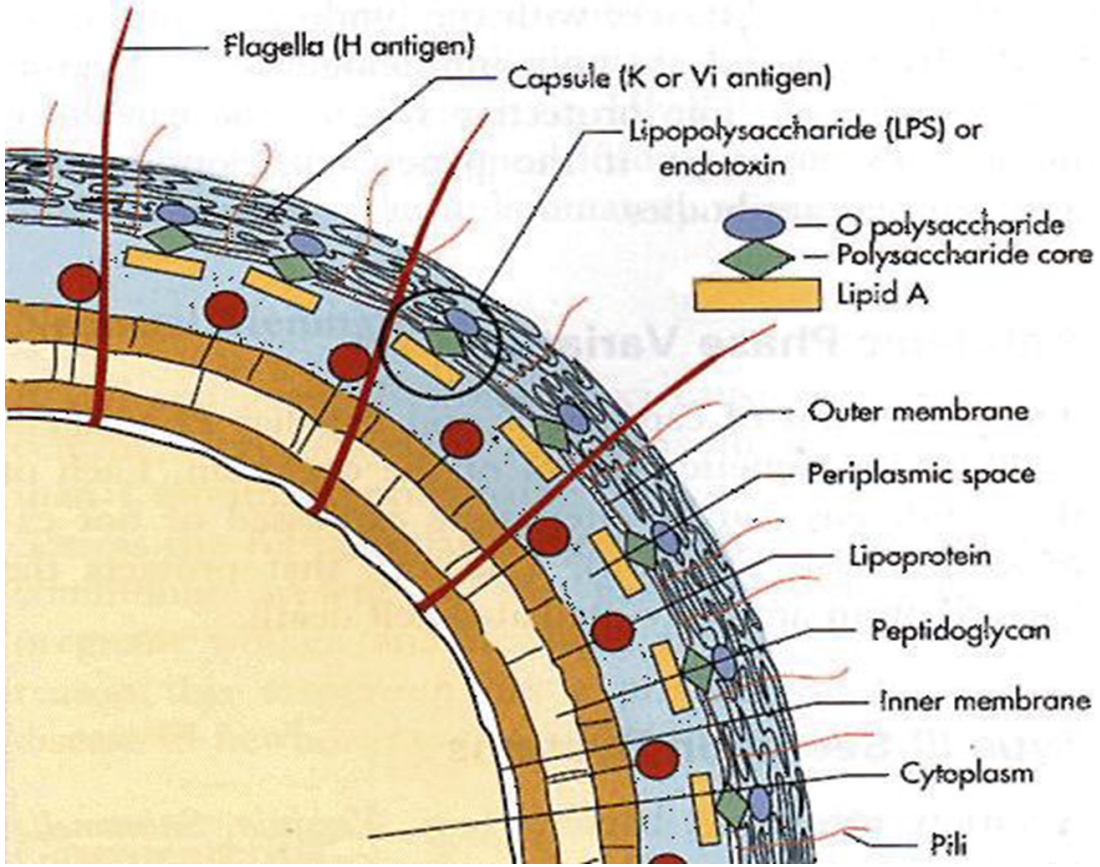
-Capsules are large and regular in *Klebsiella*, less so in *Enterobacter*, and uncommon in the other species.



Antigenic Structure :

Enterobacteriaceae have a complex antigenic structure. They are classified by:

- -More than 150 different heat-stable somatic O (lipopolysaccharide) antigens.
- - More than 100 heat-labile K (capsular) antigens. In *Salmonella typhi,* the capsular antigens are called Vi antigens.
- - More than 50 H (flagellar) antigens .



- **Colicins (Bacteriocins)**

Many gram-negative organisms produce bacteriocins. These high-molecular-weight bactericidal proteins are produced by certain strains of bacteria active against some other strains of the same or closely related species. Their production is controlled by plasmids. Colicins are produced by *E coli*. Bacteriocin-producing strains are resistant to their own bacteriocin; thus, bacteriocins can be used for "typing" of organisms.

- **Toxins & Enzymes**

Most gram-negative bacteria possess complex lipopolysaccharides in their cell walls. These substances, cell envelope (cytoplasmic membrane, peptidoglycan, outer membrane) endotoxins. Many gram-negative enteric bacteria also produce exotoxins of clinical importance.

- **Human pathogen :**

Enterobacteriaceae as a group were originally divided into pathogens and non-pathogens based on their ability to cause diarrheal disease of humans.

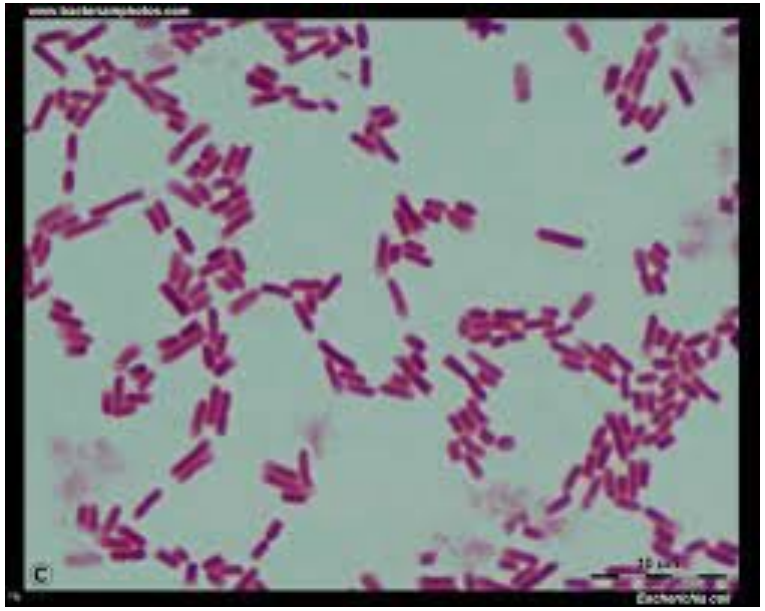
The most important pathogenic genera are *Salmonella* and *Shigella.* However, it is now known that *E. coli* causes at least five types of gastrointestinal disease in humans.

1.Escherichia coli :

- Most *E. coli* strains are harmless however there are strains that cause disease in humans and animals that making them important pathogens in their own right.

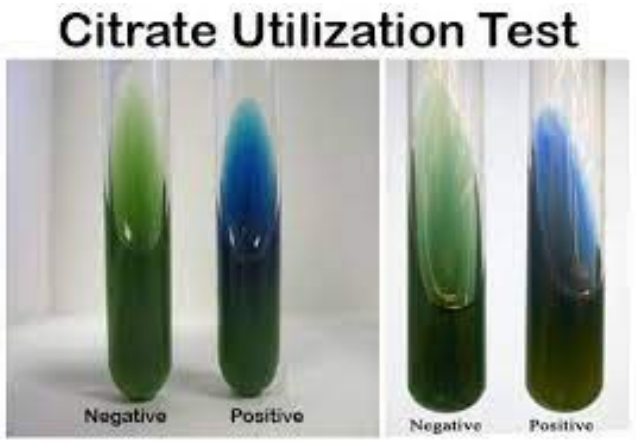
Clinically, two distinct types of pathogenic *E. coli* are recognized.

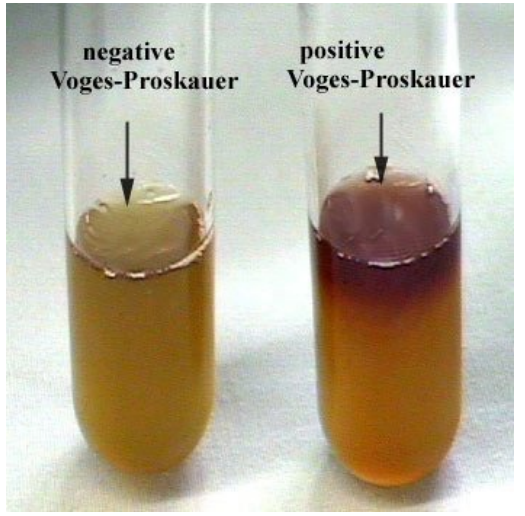
- Extra-intestinal pathogenic *E. coli* (ExPEC) includes those *E. coli* associated with newborn meningitis (NBM) or sepsis and urinary tract infections (UTIs).

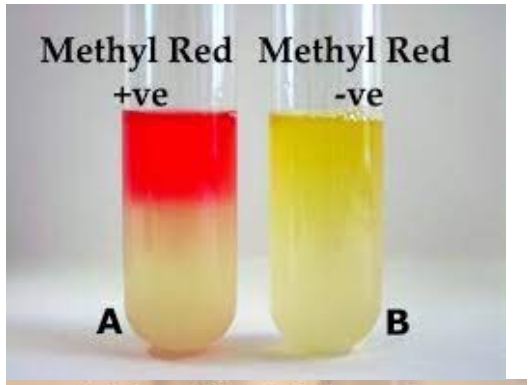


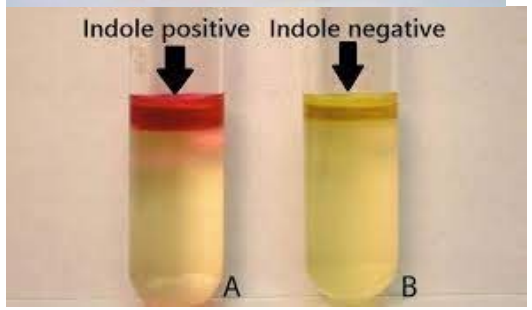
- Intestinal pathogenic *E. coli* (IPEC) includes *E. coli* responsible for a range of distinct classes of diarrhoeal disease.

- This bacteria produce pink (lactose positive) colony with surrounding pink area on MacConkey*, Ferments glucose,* lactose, trehalose, & xylose, Positive indole and methyl red tests, Does NOT produce H2S or phenylalanine deaminase, Simmons citrate negative, Usually motile, Voges-Proskauer test negative.









The strains that associated with gastrointestinal disease are classified as follow:

- **Enteroinvasive E. coli (EIEC) :**

Strains belonging to this group are biochemically, genetically and pathogenically closely related to *Shigella* spp. The most common symptom is watery diarrhoea which may precede dysenteric stools containing mucus and blood. In severe cases, the bacteria may attack the colonic mucosa, invading epithelial cells, multiplying and causing ulceration of the bowel.

- **Enterotoxigenic *E. coli* (ETEC) :**

Strains belonging to the ETEC pathotype are characterized by the production of at least one of two types of enterotoxin: LT (heat-labile enterotoxin) and ST (heat-stable enterotoxin). Cause “traveler’s diarrhea”; watery diarrhea without blood; self-limiting; usually not identified**.**

- **C-Enteroaggregative *E. coli* (EAEC*) :***

Cause diarrhea by adhering to the mucosal surface of the intestine; watery diarrhea; symptoms may persist for over two weeks, EAggEC (or EAEC) are a major cause of chronic infantile diarrhoea and they have also emerged as a cause of diarrhoeal disease in adults and children in developed countries. Toxins that have also been associated with strains of EAggEC include an *E. coli* heat-stable-like enterotoxin termed enteroaggregative heat-stable toxin-1 (EAST-1) and a heat-labile toxin.

- **D-Enteropathogenic *E. coli* (EPEC) :**

Primarily in infants and children; outbreaks in hospital nurseries and day care centers; stool has mucous but not blood; identified by serotyping.

- **E-Enterohaemorrhagic *E. coli* (EHEC) :**

(EHEC serotype 0157:H7) – associated with hemorrhagic diarrhea and hemolytic-uremic syndrome (HUS), which includes low platelet count, hemolytic anemia, and kidney failure; potentially fatal, especially in young children; undercooked hamburger, unpasteurized milk and apple cider have spread the infection; does NOT ferment sucrose; identified by serotyping. EHECs have emerged as one of the most important threats to human health .

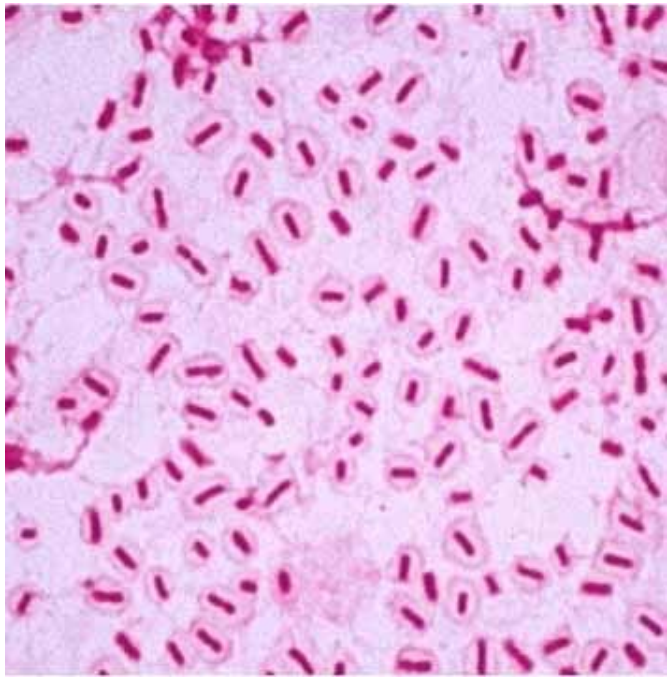
Term	Abbreviation	Pathogenic Phenotype	Signs& Symptoms
Enterotoxigenic *E.coli*	ETEC	Secretion of: heat-Labile (LT)/ heat-stable (ST)/	Traveler's diarrhoea Watery, mild abdominal cramp ,(small intestine) dehydration,vomiting
Enteroaggregative E.*coli*	EaggEC	Adhere to epith.cells	Watery diarrhoea, vomit, dehydration, abdominal pain
Enteropathogenic *E.coli*	EPEC	Adhere to epithelial cells (pilli)/effacing lesions	Infants (18-24month); low fever,malaise,vomiting, diarrhoea→ (duodenum)
Enteroinvasive *E.coli*	EIEC	Invade colonic mucosa ;Causing dysenteric-like diarrhoea	Dysentery;fever, colitis,diarrhoea with blood, mucus, Leukocytes
Enterohaemorrhagic *E.coli*	EHEC	Production of cytotoxin serotype 0157;H7	Bloody diarrhoea,WBCs, →Haemorrhagic.colitis &Haemolytic uraemic syndrome (HUS)/Acute renal failure

- ***2- Klebsiella*:**

It is gram negative , non-motile, capsulate, thick& bacilli producing mucoid pink colonies on MacConky medium, it is found in mucosa of upper respiratory tract, intestinal & urinary tract , it is member of Normal flora that may cause sever systemic infection under certain condition such as immunocompromise debilitation.

- ***Klebsiella pneumoniae***

Is the causative agent of pneumonia &lung abscesses also may cause urinary tract infections .



- **Virulence factor for *Klebsiella pneumoniae***

1-capsular mucoid polysaccharide which can resist to action of phagocytes.

2-some strain carry plasmid coding for production heat – stable enterotoxine

3-they contain resistance plasmids (R-plasmids) which confer resistance to antibiotic.

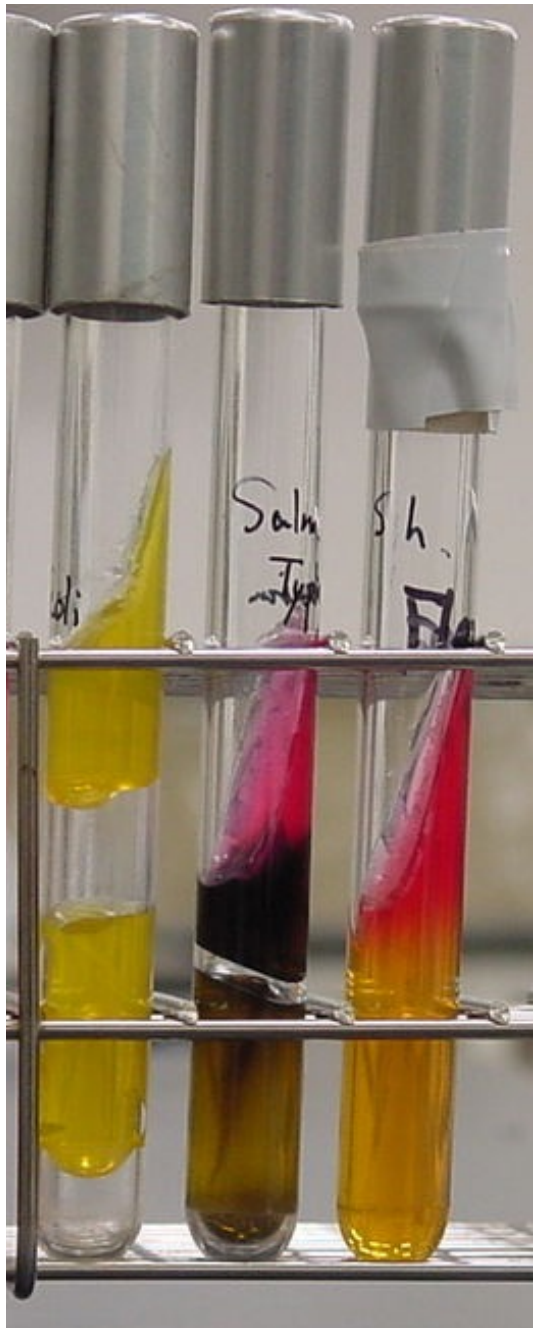
- ***3- Proteus*:**

Proteus species move very actively by means of peritrichous flagella, resulting in "swarming" on solid media.

Strains of Proteus vary greatly in antibiotic sensitivity. *P mirabilis* is often inhibited by penicillins; the most active antibiotics for other members of the group are aminoglycosides and cephalosporins. *Proteus* species are urease-positive, ferments lactose very slowly or not at all.

- **Pathogenecity:** it is opportunistic pathogen cause urinary tract infection ,may produce Pyogenic lesion like abscess infection of wound ,ear or respiratory tract.

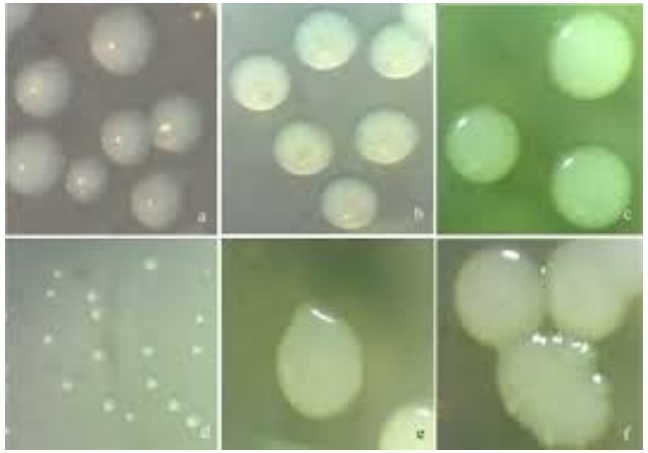
- **4. *Shigella*—**Shigellae are nonmotile and usually do not ferment lactose but do ferment other carbohydrates like glucose, producing acid but not gas. They do not produce H_2S (in triple sugar iron test). The four *Shigella* species are closely related to *E coli.*



The natural habitat of shigella is limited to the intestinal tracts of humans and other primates, where they produce bacillary dysentery.

- **Morphology & Identification**

Shigella are slender gram-negative rods; coccobacillary forms occur in young cultures.



- **Culture :**

Shigella are facultative anaerobes but grow best aerobically. Convex, circular, transparent colonies with intact edges reach a diameter of about 2 mm in 24 hours.

Pathogenesis & Pathology

- *Shigella* infections are almost always limited to the gastrointestinal tract; bloodstream invasion is quite rare.
- The essential pathologic process is :-

-Invasion of the mucosal epithelial cells (eg, M cells) by induced phagocytosis

-Escape from the phagocytic vacuole.

-Multiplication and spread within the cell cytoplasm, and passage to adjacent cells.

- This bacteria cause micro abscesses in the wall of the large intestine and terminal ileum lead to necrosis of the mucous membrane, superficial ulceration, bleeding, and formation of a "pseudomembrane" on the ulcerated area. This consists of fibrin, leukocytes, cell debris, a necrotic mucous membrane, and bacteria.

Toxins

- **Endotoxin :**

all shigellae release their toxic lipopolysaccharide. This endotoxin probably contributes to the irritation of the bowel wall.

- ***Shigella dysenteriae* exotoxin :**

S. dysenteriae type 1 (Shiga bacillus) produces a heat-labile exotoxin that affects both the gut and the central nervous system. The exotoxin is:

- Acting as an enterotoxin, it produces diarrhea as does the *E coli* toxin

- inhibits sugar and amino acid absorption in the small intestine.

-Acting as a "neurotoxin," this material may contribute to the extreme severity and fatal nature of *S dysenteriae* infections.

Diagnostic Laboratory Tests

- **Specimens :**

Specimens include fresh stool, and rectal swabs for culture. Large numbers of fecal leukocytes and some red blood cells often are seen microscopically.

- **Culture :**

The materials are streaked on differential media (eg, MacConkey or EMB agar) and on selective media (Hektoen enteric agar or *Salmonella-Shigella* agar).

Colorless (lactose-negative) colonies are inoculated into triple sugar iron agar.

Organisms that fail to produce H_2S, that do not produce gas in triple sugar iron agar medium, and that are nonmotile should be subjected to slide agglutination by specific *Shigella* antisera.

- **Treatment :**

Ciprofloxacin, ampicillin, doxycycline, and trimethoprim-sulfamethoxazole are most commonly inhibitory for *Shigella* isolates and can suppress acute clinical attacks of dysentery and shorten the duration of symptoms.

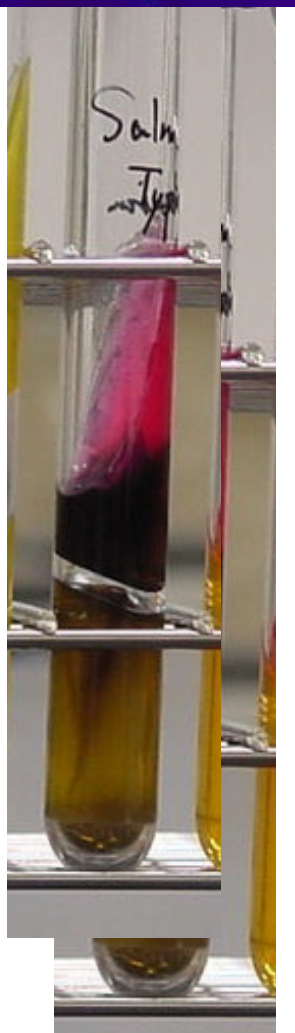
5. *Salmonella*—They are pathogenic for humans or animals when ingested.

Salmonella are transmitted from animals and animal products to human, where they cause **enteritis, systemic infection, and enteric fever.**

- **Morphology & Identification :**

Salmonella vary in length. Most isolates are motile with peritrichous flagella.

Salmonellae grow on simple media, it ferments glucose and mannose without producing gas but they almost never ferment lactose or sucrose. They usually produce H_2S. They survive freezing in water for long periods. Salmonellae are resistant to certain chemicals (eg, brilliant green, sodium tetrathionate, sodium deoxycholate) .



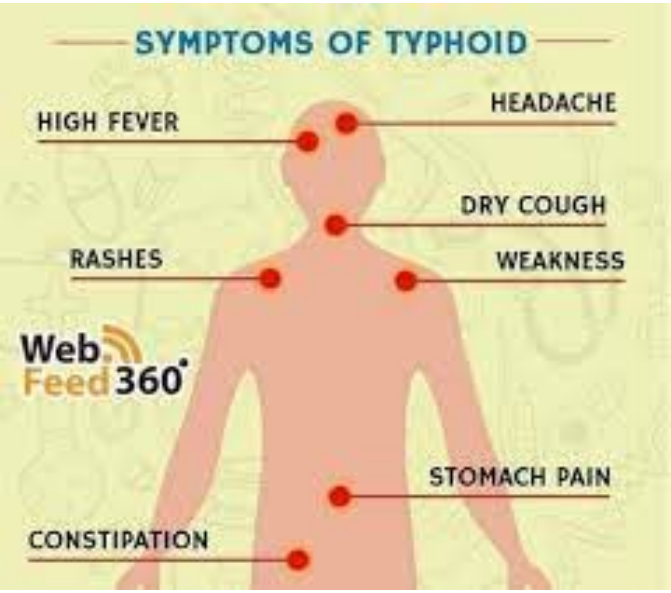
Pathogenesis & Clinical Findings :

- *Salmonella typhi*, *Salmonella choleraesuis*, *Salmonella paratyphi* A and *Salmonella paratyphi* B are primarily infective for humans. The vast majority of salmonellae, however, are chiefly pathogenic in animals that constitute the reservoir for human infection: poultry, pigs, rodents, cattle, pets (from turtles to parrots), and many others.

- The organisms almost always enter via the oral route, usually with contaminated food or drink. The infective dose to produce clinical or subclinical infection in humans is 10^5–10^8 salmonellae (but perhaps as few as 10^3 *Salmonella* Typhi organisms).

Salmonellae produce three main types of disease in humans, but mixed forms are frequent

1-THE "ENTERIC FEVERS" (TYPHOID FEVER)



This syndrome is produced by only a few of the salmonellae, of which *Salmonella* Typhi (typhoid fever) is the most important. The ingested salmonellae reach the small intestine, from which they enter the lymphatics and then the bloodstream. They are carried by the blood to many organs, including the intestine. The organisms multiply in intestinal lymphoid tissue and are excreted in stools.

After an incubation period of 10–14 days, fever, malaise, headache, constipation, bradycardia, and myalgia occur. The spleen and liver become enlarged. Rose spots, usually on the skin of the abdomen or chest, are seen briefly in rare cases. The white blood cell count is normal or low. the mortality rate was 10–15%. Treatment with antibiotics has reduced the mortality rate to less than 1%.

2- BACTEREMIA WITH FOCAL LESIONS

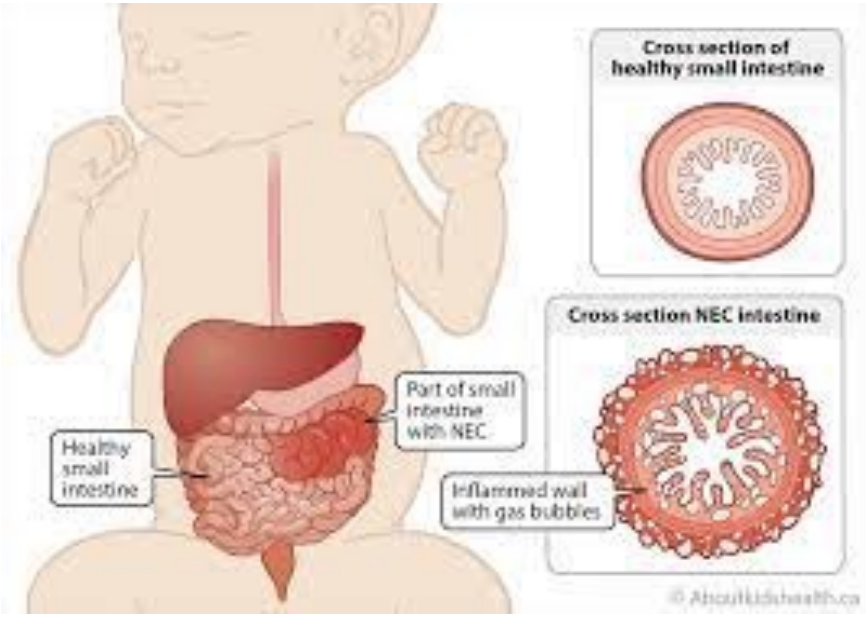
This is associated commonly with *S.choleraesuis* but may be caused by any salmonella serotype. Following oral transmission, there is early invasion of the bloodstream (with possible focal lesions in lungs, bones, meninges, etc) intestinal manifestations are often absent. Blood cultures are positive.

3- ENTEROCOLITIS

This is the most common manifestation of salmonella infection. Eight to 48 hours after ingestion of salmonellae, there is nausea, headache, vomiting, and profuse diarrhea, with few leukocytes in the stools. Low-grade fever is common, but the episode usually resolves in 2–3 days. Inflammatory lesions of the small and large intestine are present.

Bacteremia is rare (2–4%) except in immunodeficient persons.

Blood cultures are usually negative, but stool cultures are positive for salmonellae and may remain positive for several weeks after clinical recovery.



Diagnostic Laboratory Tests

- **Specimens**

Blood for culture must be taken repeatedly. In **enteric fevers and septicaemias**, blood cultures are often positive in the first week of the disease. Bone marrow cultures may be useful. Urine cultures may be positive after the second week.

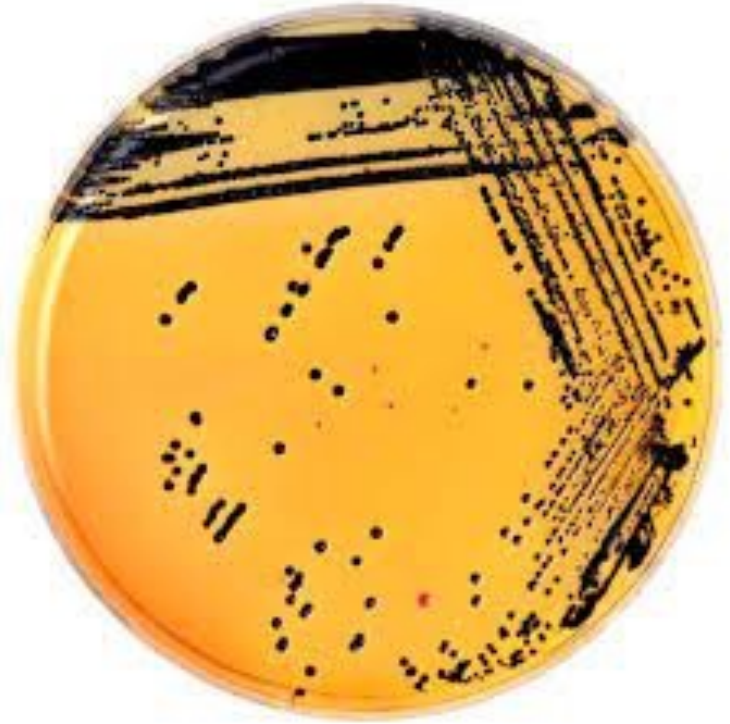
Stool specimens also must be taken repeatedly. In enteric fevers, the stools yield positive results from the second or third week on; in enterocolitis, during the first week.

Bacteriologic methods for isolation of salmonellae

- **1. Differential medium cultures— (**Differential media are used to differentiate closely related organisms or groups of organisms).

EMB, MacConkey, or deoxycholate medium permits rapid detection of lactose non-fermenters (not only salmonellae and shigellae but also *Proteus*, *Serratia*, etc).

Bismuth sulfite medium permits rapid detection of salmonellae which form black colonies because of H_2S production. Many salmonellae produce H_2S.

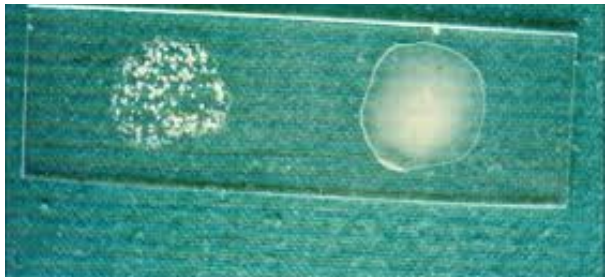


- **2. Selective medium cultures—** (Selective media allow certain types of organisms to grow, and inhibit the growth of other organisms). For salmonella, The specimen is plated on salmonella-shigella (SS) agar, Hektoen enteric agar which favor growth of salmonellae and shigellae over other Enterobacteriaceae.

- **3. Enrichment cultures—**The specimen (usually stool) also is put into tetrathionate broth, which inhibit replication of normal intestinal bacteria and permit multiplication of salmonellae. After incubation for 1–2 days, the resulted colonies have to be plated on differential and selective media.
- **4. Final identification—**Suspect colonies from solid media are identified by biochemical reaction patterns and slide agglutination tests with specific sera.

SEROLOGIC METHODS

1. **Agglutination test—**In this test, known sera and unknown culture are mixed on a slide.

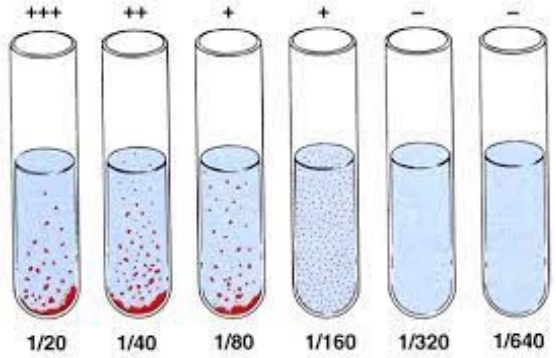


Clumping, when it occurs, can be observed within a few minutes.

This test is particularly useful for rapid identification of cultures.

There are commercial kits available to agglutinate and serogroup salmonellae by their O antigens: A, B, C_1, C_2, D, and E.

2. Tube dilution agglutination test (Widal test)—The Widal test to detect these antibodies against the O and H antigens has been in use for decades.



At least two serum specimens, obtained at intervals of 7–10 days, are needed to prove a rise in antibody titre.

Serial dilutions of unknown sera are tested against antigens from representative salmonellae. False-positive and false-negative results occur.

Serum agglutinins rise sharply during the second and third weeks of *Salmonella* Typhi infection.

Treatment :

- While enteric fevers and bacteraemia with focal lesions **require antimicrobial treatment**, the vast majority of cases of enterocolitis do not.
- Antimicrobial treatment of *Salmonella* enteritis in neonates is important.
- In severe diarrhea, replacement of fluids and electrolytes is essential.
- Antimicrobial therapy of invasive *Salmonella* infections is with ampicillin, trimethoprim-sulfamethoxazole, or a third-generation cephalosporin.
- Multiple drug resistance transmitted genetically by plasmids among enteric bacteria is a problem in *Salmonella* infections.
- Susceptibility testing is an important in order to select a proper antibiotic.

- **Carriers :**

After manifest or subclinical infection, some individuals continue to harbour salmonellae in their tissues for variable lengths of time (healthy permanent carriers). harbouring the organisms in the gallbladder, biliary tract, or, rarely, the intestine or urinary tract.

Sources of infection :

The sources of infection are food and drink that have been contaminated with salmonella. The following sources are important:

1. Water—Contamination with feces often results in explosive epidemics.

2. Milk and other dairy products (ice cream, cheese, custard)— Contamination with feces and inadequate pasteurization or improper handling.

3. Shellfish—From contaminated water.

4. Dried or frozen eggs—From infected fowl or contaminated during processing.

5. Meats and meat products—From infected animals (poultry) or contamination with feces by rodents or human

- **Prevention & Control** salmonella infections

1-prevent contamination of food and water by rodents or other animals that excrete salmonellae.

2-Infected poultry, meats, and eggs must be thoroughly cooked.

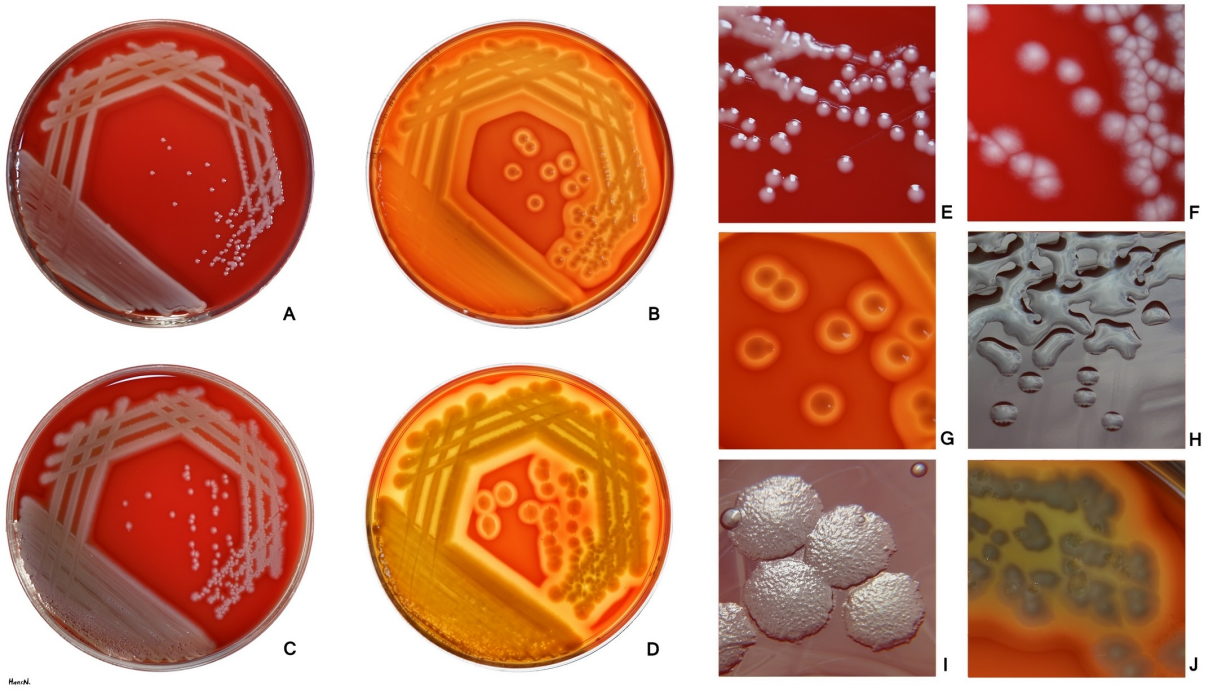
3-Carriers must not be allowed to work as food handlers and should observe strict hygienic precautions.

4-Two typhoid vaccines are currently available: an oral live, attenuated vaccine and a Vi capsular polysaccharide vaccine for intramuscular use.

5-Vaccination is recommended for travellers to endemic regions.

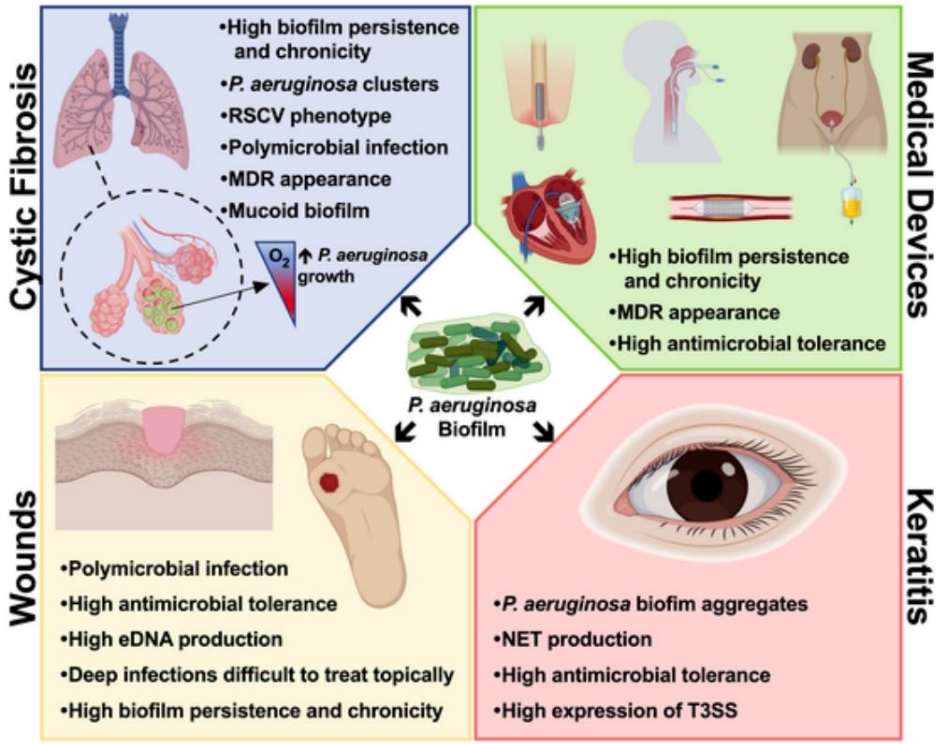
Pseudomonas aeruginosa

- ***Pseudomonas aeruginosa*** is a common encapsulated, Gram-negative, strict aerobic (although can grow anaerobically in the presence of nitrate), Rod-shaped bacterium that can cause disease in plants and animals, including humans.



Its medical importance is attributed to:

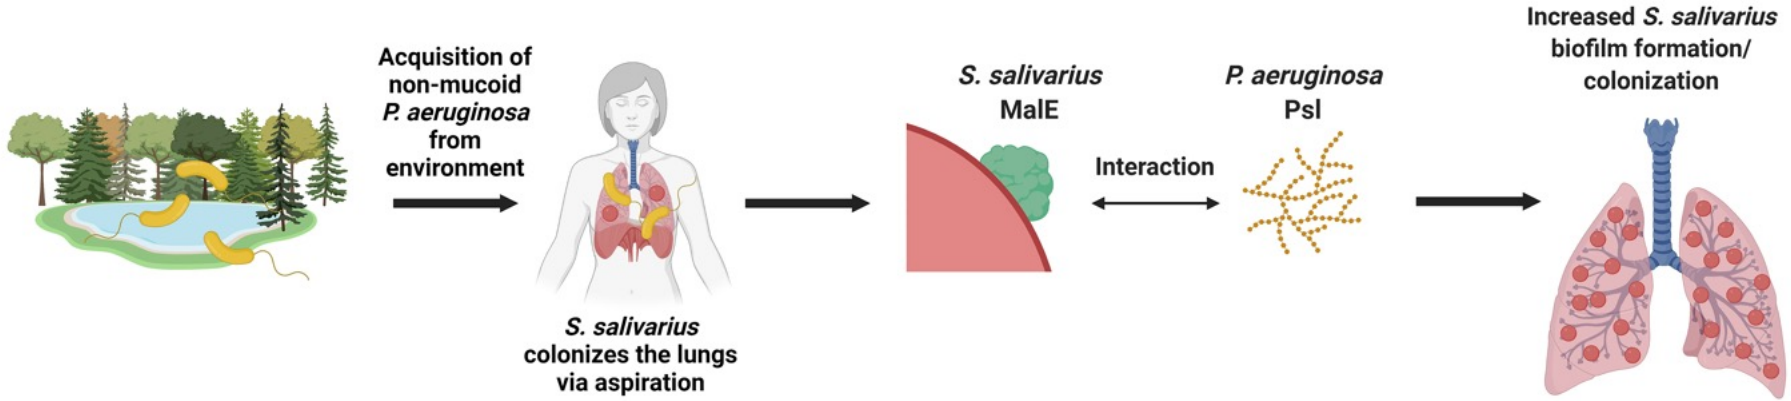
- *P. aeruginosa* is a multidrug resistant pathogen due to its advanced antibiotic resistance mechanisms.
- its association with serious illnesses – hospital-acquired infections such as ventilator-associated pneumonia and various sepsis syndromes.
- Infections are Nosocomial catheterized patients, respiratory tract infections (cystic fibrosis), urinary tract infections, wound infections, and eye infection (keratitis).



- The organism is considered opportunistic as serious infection often occurs during existing diseases
- It generally affects the immunocompromised but can also infect the immunocompetent. The symptoms of such infections are generalized inflammation and sepsis.
- If such colonizations occur in critical body organs, such as the lungs, the urinary tract, and kidneys, the results could be fatal.
- Treatment of *P. aeruginosa* infections can be difficult due to its natural resistance to antibiotics.

- Treatment of *P. aeruginosa* infections can be difficult due to its natural resistance to antibiotics.
- *However, P. aeruginosa* is not extremely virulent in comparison with other major pathogenic bacterial species – for example the Gram-positive *Staphylococcus aureus* and *Streptococcus pyogenes*
- *P. aeruginosa* is capable of extensive colonization, and can aggregate into enduring biofilms.

- It is citrate, catalase, and oxidase positive. It is found in soil, water, skin flora, and most man-made environments throughout the world.
- It thrives not only in normal atmospheres, but also in low-oxygen atmospheres, thus has colonized many natural and artificial environments.



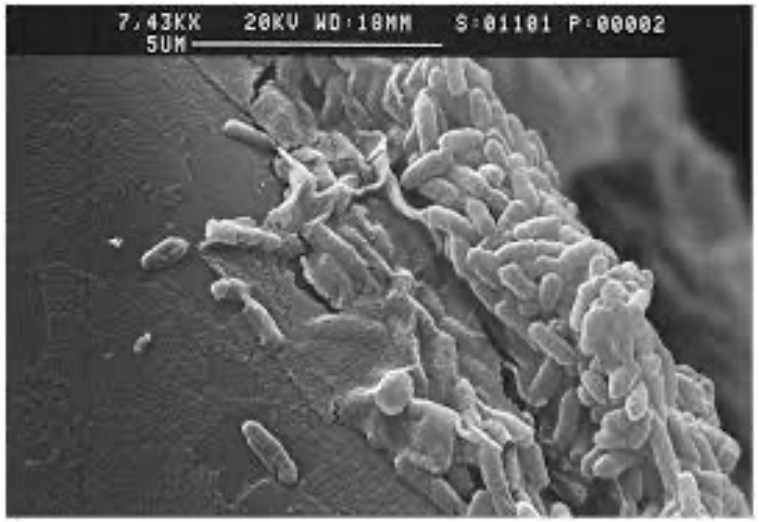
Toxins

- *P. aeruginosa* uses the virulence factor exotoxin A to inactivate eukaryotic elongation factor 2 in the host cell, much as the diphtheria toxin does. Without elongation factor 2, eukaryotic cells cannot synthesize proteins and necrotise.

- *P. aeruginosa* uses an exoenzyme U (ExoU), which degrades the plasma membrane of eukaryotic cells, leading to lysis.

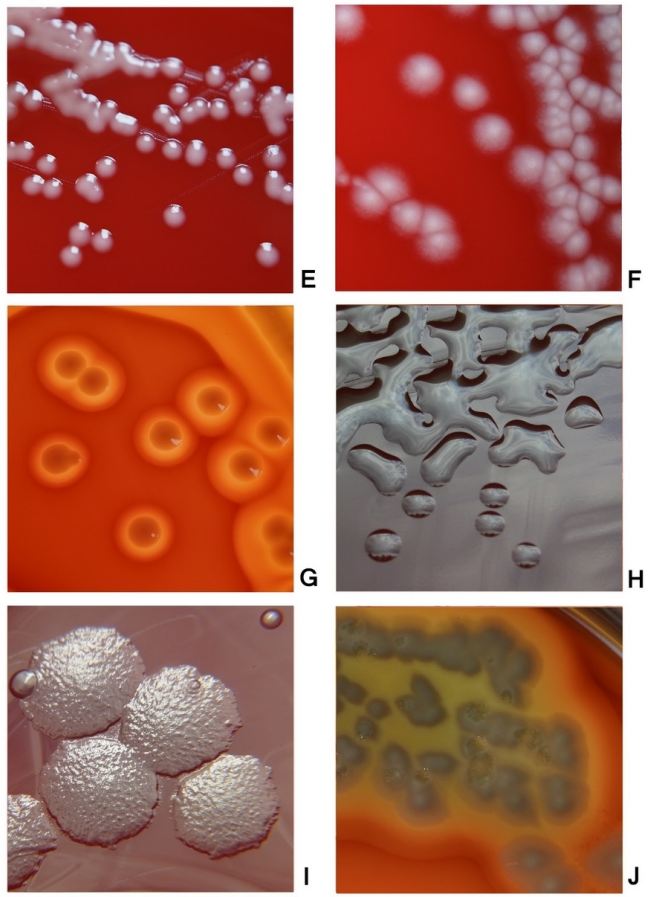
Biofilms formation

- Biofilms of *P. aeruginosa* can cause chronic opportunistic infections, which are a serious problem for medical care especially for immunocompromised patients and the elderly. They often cannot be treated effectively with traditional antibiotic therapy.
- Biofilms seem to protect these bacteria from adverse environmental factors.
- Researchers consider it important to learn more about the molecular mechanisms that cause the switch from planktonic growth to a biofilm phenotype.



Diagnosis

- Depending on the nature of infection, an appropriate specimen is collected and sent to a bacteriology laboratory for identification.
- As with most bacteriological specimens, a Gram stain is performed, which may show Gram-negative rods and/or white blood cells.
- *P. aeruginosa* produces colonies with a characteristic "grape-like" on bacteriological media. In mixed cultures, it can be isolated as clear colonies on MacConkey agar, it does not ferment lactose, which will test positive for oxidase.



- Confirmatory tests include production of the blue-green pigment pyocyanin on cetrimide agar .
- A Trible sugar iron slant is often used to distinguish nonfermenting *Pseudomonas* species from enteric pathogens in faecal specimens.
- When *P. aeruginosa* is isolated from a normally sterile site (blood, bone, deep collections), it is generally considered dangerous and almost always requires treatment.

Treatment

- Many *P. aeruginosa* isolates are resistant to a large range of antibiotics and may demonstrate additional resistance after unsuccessful treatment.
- It should usually be possible to guide treatment according to laboratory sensitivities, rather than choosing an antibiotic empirically.

- Due to widespread resistance to many common first-line antibiotics, carbapenems, polymyxins, and more recently tigecycline were considered to be the drugs of choice.
- however, resistance to these drugs has also been reported. Despite this, they are still being used in areas where resistance has not yet been reported.
- Use of β-lactamase inhibitors such as **sulbactam (** beta-lactamase inhibitors) has been advised in combination with antibiotics to enhance antimicrobial action even in the presence of a certain level of resistance.

- *P. aeruginosa* low antibiotic susceptibility is attributable to a concerted action of multidrug efflux pumps with chromosomally encoded antibiotic resistance genes
- Efflux pumps are capable of moving a variety of different toxic compounds out of cells, such as antibiotics,
- Moreover, *P. aeruginosa* have low permeability of the bacterial cellular envelopes
- In addition to this intrinsic resistance, *P. aeruginosa* easily develops acquired resistance either by mutation in chromosomally encoded genes or by the horizontal gene transfer of antibiotic resistance determinants.
- Hypermutation favours the selection of mutation-driven antibiotic resistance in *P. aeruginosa* strains producing chronic infections.

Prevention

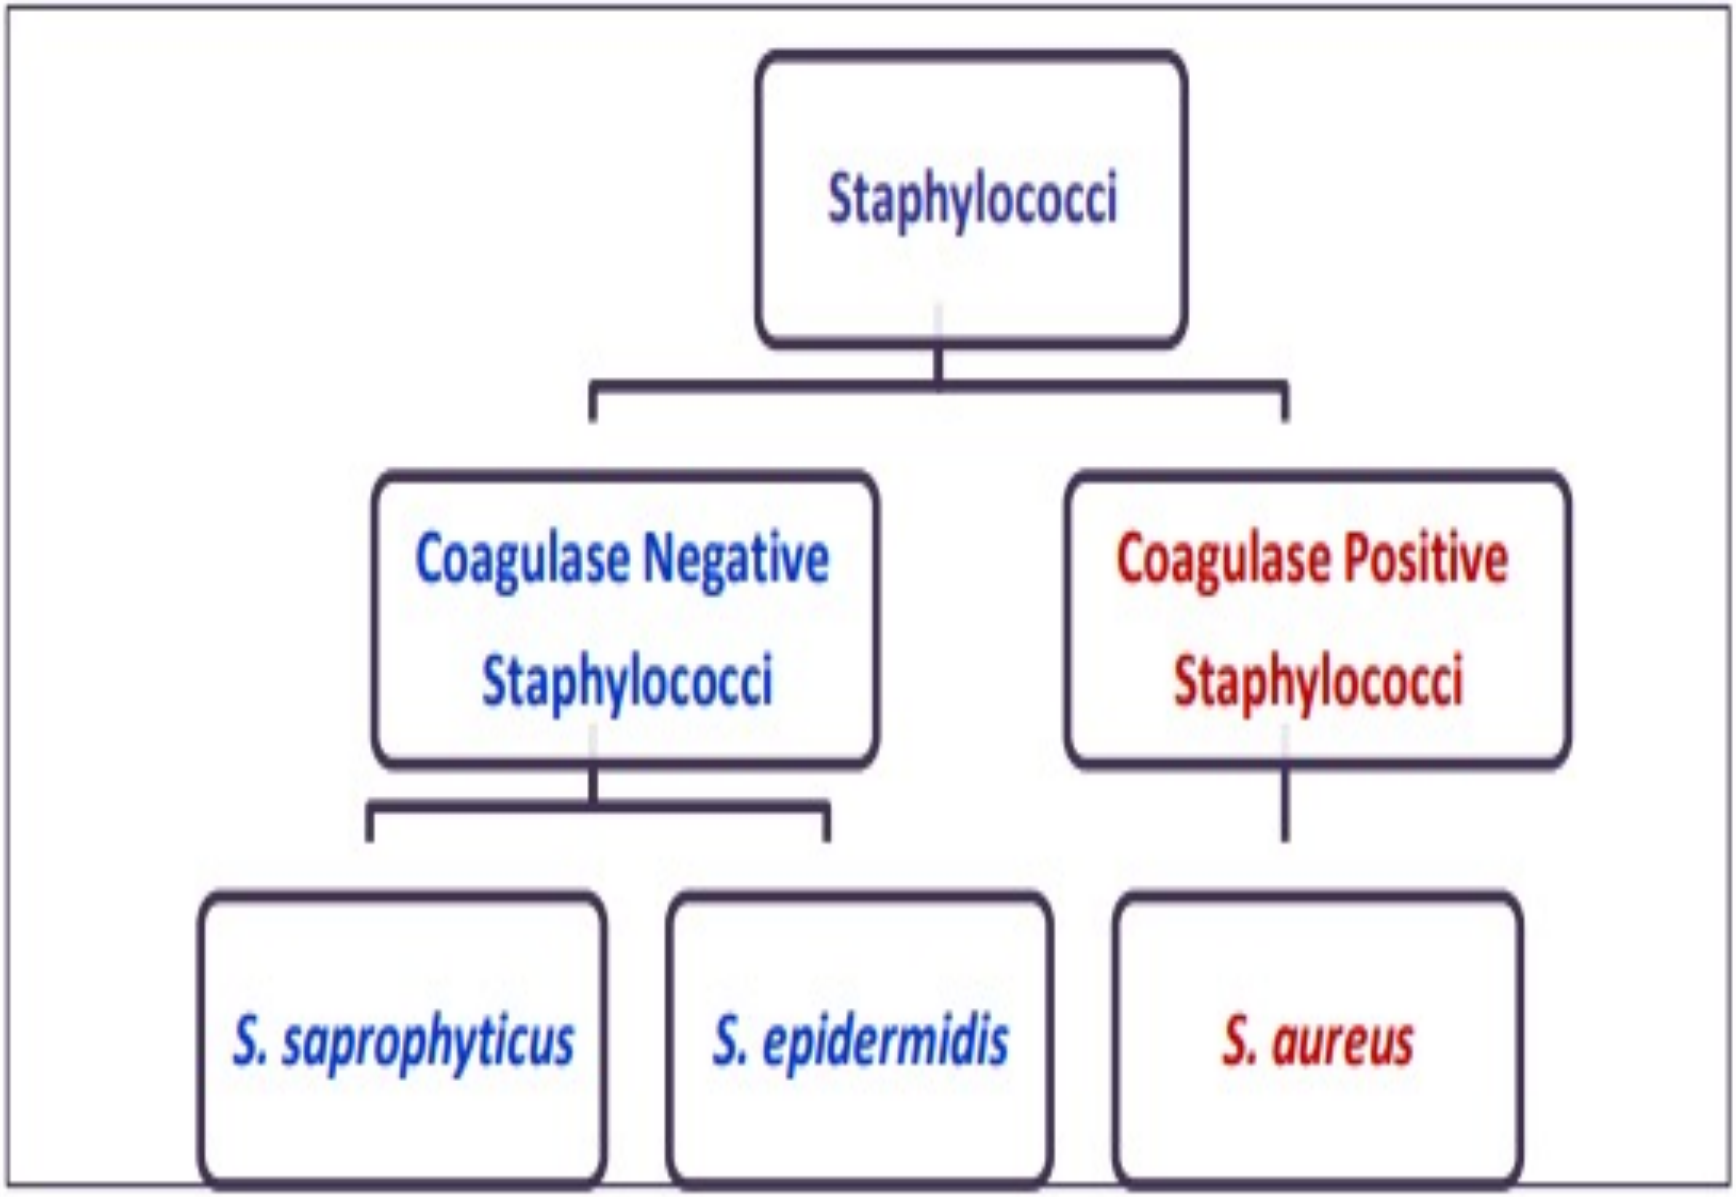
- Probiotic prophylaxis may prevent colonization and delay onset of *Pseudomonas* infection in an ICU setting. Immunoprophylaxis against *Pseudomonas* is being investigated. The risk of contracting *P. aeruginosa* can be reduced by avoiding pools, hot tubs, and other bodies of standing water, as well as individual hygiene.

Staphylococcus

Staphylococcus

- Family: Micrococcaceae
- Genus:
  - *Staphylococcus*- **the name** derived from Greek word "staphyle" (means bunch of grapes)

  This genus Include major human pathogen and skin commensals bacteria
  - *Micrococcus*- skin commensal



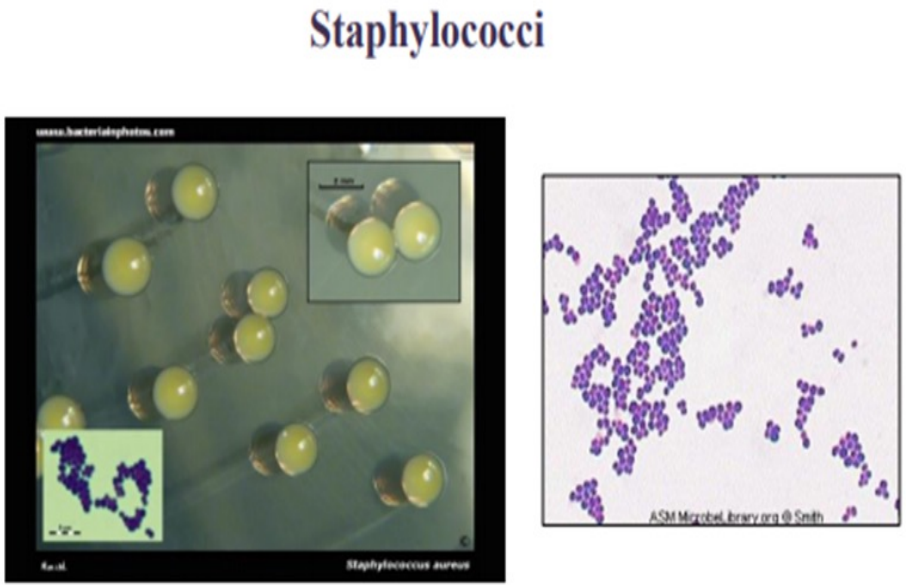
Staphylococci
Coagulase Negative Staphylococci
Coagulase Positive Staphylococci
S. saprophyticus
S. epidermidis
S. aureus

Staphylococcus: General Characteristics

- Gram-positive spherical cells (0.5-1.5 μm) in singles, pairs, and clusters "bunches of grapes"

Gold colonies on tryptic soy agar

These bacteria are G+ so its color is purple in Gram-stained smear



Staphylococcus: General Characteristics

- Non motile
- Non–spore-forming
- Catalase-producing
- Grow at 15 % NaCl concentrations.
- Oxidase: negative
- Glucose fermenters
- Primarily aerobic, some facultatively anaerobic

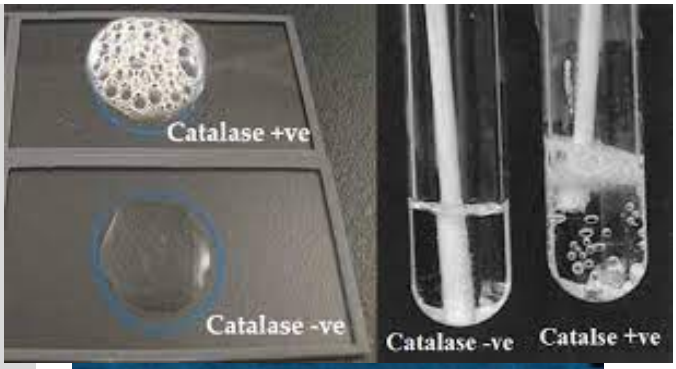
Staphylococcus: General Characteristics

- Staphylococcus divided into **coagulase positive & coagulase negative** categories
- Colony morphology: buttery looking, cream or white colored on blood agar and Gold colonies on tryptic soy agar

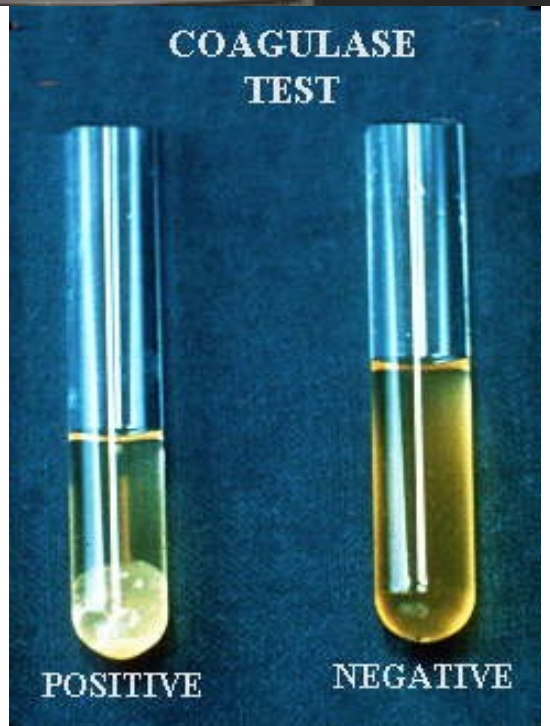
- Optimum temperature at 37°C , however they can grow at a temperature ranged from (15 to 45 °C).
- Some produce Beta-hemolytic colonies on blood agar.
- For Staphylococcus aureus the name (aureus) refers to the gold color of the colonies.

Staphylococcus: General Characteristics

All staphylococci are Catalase positive. (Catalase converts H_2O_2 to H_2O and O_2)



-The **coagulase** (Coagulase converts fibrinogen to fibrin) and manifold fermentation tests are used to distinguish *S. aureus* from other staphylococcal species.



- Non-Motile and Non spore forming.

Coagulase Negative Staphlyococci (CoNS)

-Are part of normal flora of human skin and mucous membranes

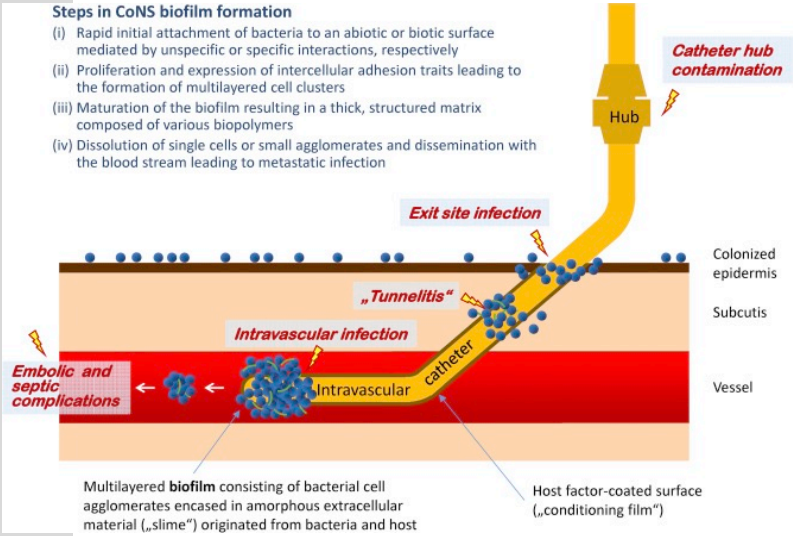
- relatively low virulence

- frequently involved in nosocomial and opportunistic infections

- Clinically significant infection associated with endocarditis, joints infection, wound infections, bacteremia, Urinary tract infections (UTI).

Coagulase Negative Staphlyococci (CoNS)

- *S. epidermidis* is an inhabitant of the skin and mucous membranes, mostly nonpathogenic & may play a protective role in humans as normal flora.
- Adherence and colonization of catheters by *S. epidermidis* is a crucial step in the initiation of foreign body infections.
- The production of biofilm, a significant determinant of virulence for *S. epidermidis.*
- *S. saprophyticus* is a leading cause of cystitis in young women. And shares of urinary tract infection



Coagulase Positive Staphylococci (CoPS)

- *S. aureus* can be found in nasal passage as normal flora, but it may be found in other sites (skin, mucous membranes, oral cavity & gastrointestinal tract)
- Always considered a potential pathogen and it significantly can cause nosocomial infections.
- populations known to be at risk of staphylococcal disease including dialysis patients, diabetics and HIV-infected subjects.
- Staphylococci cause infection either as a result of autoinoculation or by transmission from a carrier to a patient.

Staphylococcus aureus

- ***S. aureus* causes a variety of suppurative (pus-forming) and toxigenic infections in humans.**

Staphylococcus aureus

- **These bacteria can produce Superficial skin lesions such as Boils, furuncles, abscess**
- They produce these infection Because of their presence as commensals on the skin and other sites.
- both coagulase positive and negative bacteria frequently cause prosthetic device (e.g. intravascular catheters) related infections.
- Establishment of infection in general requires an ordered sequence of events that involves adherence, colonization, invasion, spread, as well as the host response to this process.

Furuncles

Boils

Staphylococcus aureus

- **More serious skin** infections such as Impetigo (bubble-like swellings that can break and peel away; common in newborns)
- Staphylococcal scalded skin syndrome (SSSS) or Ritter's disease (relatively rare); (toxin induces bright red flush, blisters, then desquamation of the epidermis)

Staphylococcus aureus

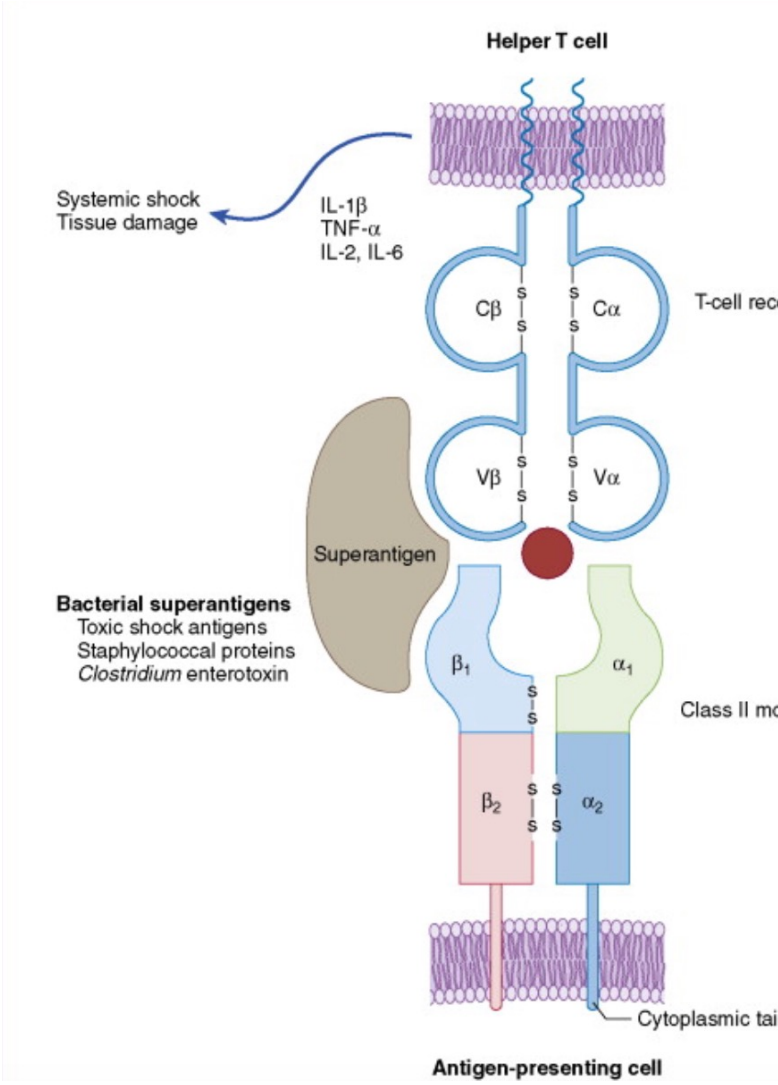
- **Could produce Serious infections (Deep)** such as Pneumonia (infections in the lung), Osteomyelitis (Localized infection of bone), endocarditis, meningitis, skeletal muscle, urinary tract infections.
- S. aureus is a major cause of hospital acquired (nosocomial) infections Surgical wounds and infections associated with medical devices. Serious consequences of staphylococcal infections (Systematic infections) occur when the bacteria invade the blood stream. A resulting septicemia may be rapidly fatal or bacteremia.

Staphylococcus aureus

- **Toxigenic infections:** S aureus causes food poisoning by releasing heat stable enterotoxins into food.
- These bacteria can produce toxic shock syndrome (leading to shock and organ failure) by release of superantigens into the blood stream.

Staphylococcus aureus

- The superantigens are T cell mitogens. Disease takes place due to the ability of these toxins to bind antigen presenting cells MHC 2 molecule outside the peptide groove. The superantigens then bind T cells via the variable region resulting in massive T cell activation and the release of large quantities of cytokines – a "cytokine storm" including IL-1, IL2, TNF, and interferon gamma. The result is a multiorgan disease similar in clinical presentation to septic shock with significant morbidity and mortality.



DISEASES

- **<u>Due to direct effect of organism</u>**
  - Local - skin
  - Deep abscesses
  - Systemic infections
- **<u>Toxin mediated</u>**
  - Food poisoning
  - toxic shock syndrome
  - Scalded skin syndrome

Staphylococcus aureus
virulence factors

(1) Surface proteins that facilitate bacterial adherence to host cell surfaces. These surface proteins facilitate attachment to molecules found in the extracellular matrix including fibronectin, fibrinogen, and collagen. They may help explain the tropism of this bacterial species to invade particular tissue sites

Staphylococcus aureus
virulence factors

- **(2) Invasions** Promote bacterial spread in tissues (leukocidin, kinases, hyaluronidase). Hyaluronidases hydrolyze hyaluronic acids and may contribute to tissue breakdown and spread of staphylococci across tissue barriers

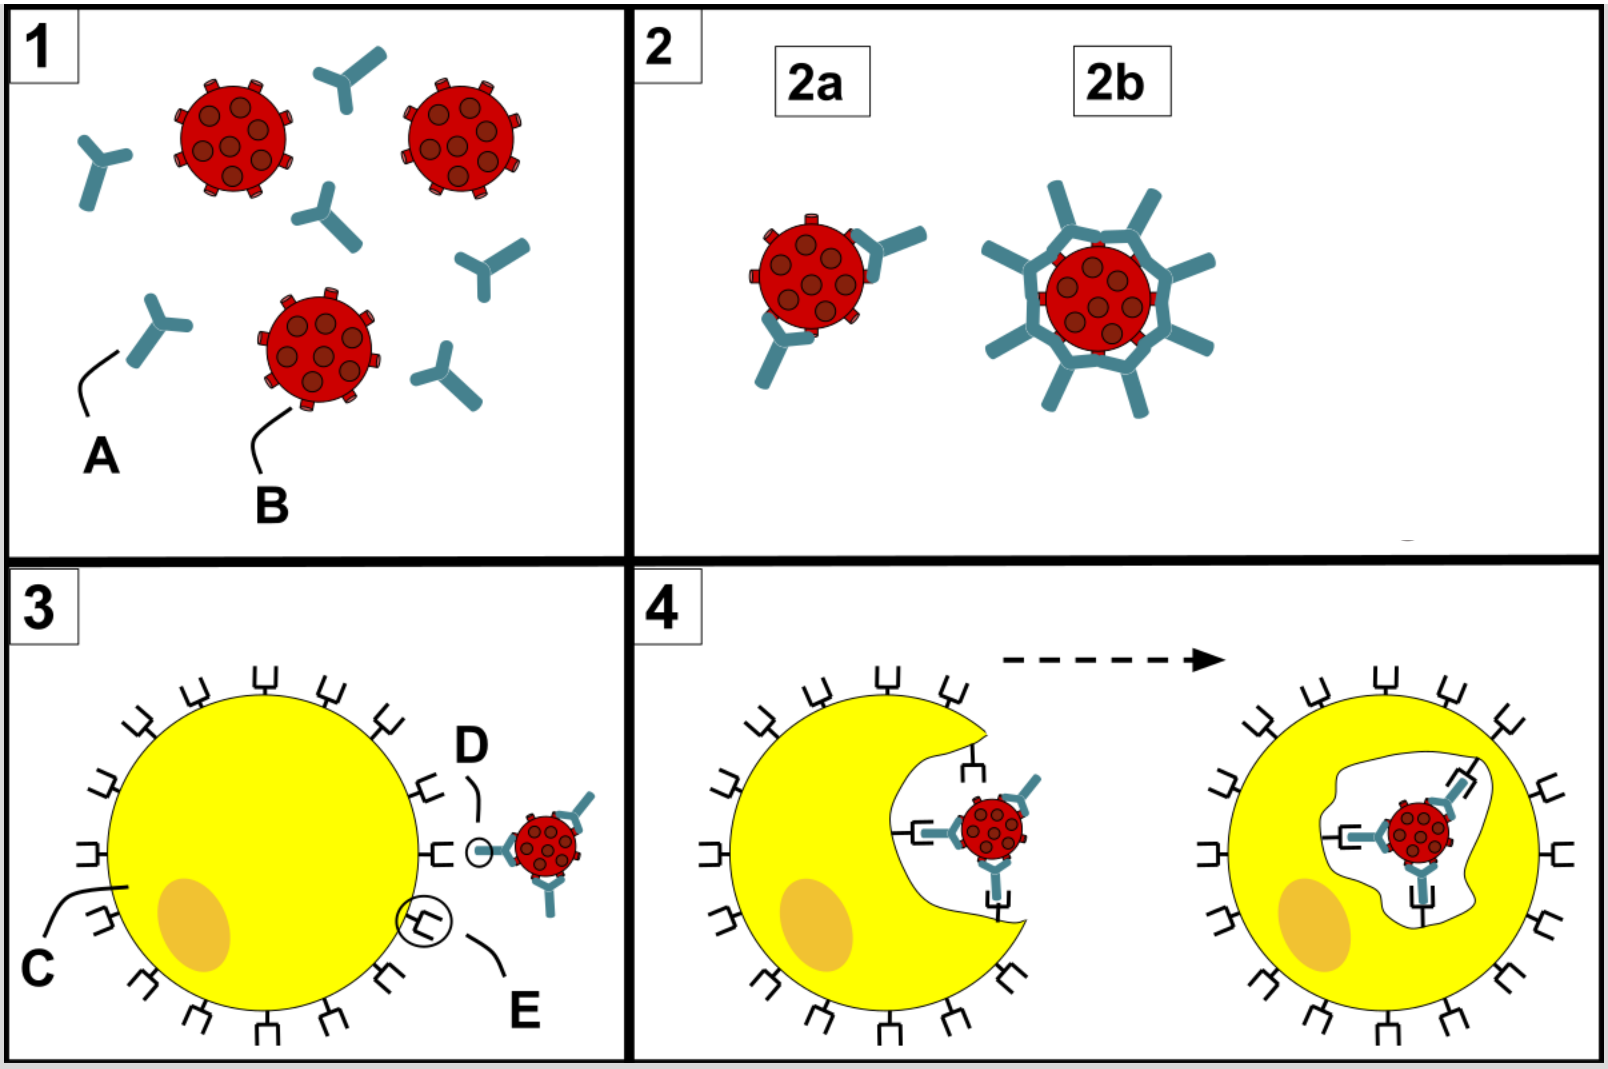
Staphylococcus aureus
virulence factors

- **(3) DNase** Digests DNA
- **(4) Lipases** Digest oils; enhances colonization on skin .
- **(5) Surface factors Avoidance of host defenses**; Inhibit phagocytic engulfment (capsule, Protein A).

Staphylococcus aureus
virulence factors

- The majority of clinical isolates of *S aureus* express a surface polysaccharide (microcapsule) which can be visualized only by electron microscopy. *S. aureus* strains isolated from infections express high levels of the capsule but rapidly lose it when cultured in the laboratory.
- **- Protein A**: binds IgG antibody in the wrong orientation (Fc region), which disrupts opsonization and phagocytosis.

Staphylococcus aureus
virulence factors



Staphylococcus aureus
virulence factors

- **(6)** Staphyloxanthin; carotenoid pigment which responsible for golden colonies, and it has an antioxidant action that helps bacteria to evade reactive oxygen species by the host immune system. Catalase production.
- **(7) Membrane-damaging toxins** Lyse eukaryotic cell membranes. Hemolysin lysis red blood cells. Leukocidin; lysis neutrophils and macrophages.

Staphylococcus aureus
virulence factors

- **Exfoliative toxins (ETs);**responsible for Staphylococcal scalded skin syndrome (SSSS); separates the epidermis from the dermis. –
- Panton-Valentine Leukocidin (PVL) cytotoxin creates pores in the membranes of infected cells. It is associated with severe necrotizing pneumonia in children.
- (**10**) Inherent & acquired resistance to antimicrobial agents (Penicillinase- inactivates penicillin).
- Beta-lactamases are released by staphylococci and can hydrolyze the beta-lactam ring of penicillins and cephalosporins rendering the antibiotics useless.

Host Defense against Staphylococcal Infections

- Phagocytosis: Neutrophil is the primary cellular defenses of innate immunity against Staphylococcal infections.
- Antibodies are produced which neutralize toxins and promote opsonization.
- Staphylococci may be difficult to kill after phagocytic engulfment because they produce catalase which neutralize the superoxide (on of reactive oxygen species) which is primary phagocytic killing mechanisms within the phagolysosome

Treatment

- Hospital acquired infection of S. aureus is often caused by antibiotic resistant strains (e.g. MRSA) and can be treated with vancomycin or an alternative.
- The term MRSA refers to Methicillin resistant S. aureus and related beta-lactam antibiotics (e.g. penicillin, oxacillin, amoxacillin). Some MRSA are resistant to vancomycin (VRSA). The infections have been treated with combination therapy using sulfa drugs and/or rifampin.
- (CoNS); can also produce beta lactamase enzyme that makes them resistant to methicillin and oxacillin. Vancomycin is the most common antibiotic used to treat infections caused by CoNS. Rifampin and gentamicin may be added to prevent highly antibiotic resistance.

- **Vaccines** :-No vaccine is generally available that stimulates active immunity against staphylococcal infections in humans.

Staphylococci and micrococci in Oral cavity

Staphylococci and micrococci are also not commonly isolated in large numbers from the oral cavity although the former are found in denture plaque, as well as in immunocompromised patients and individuals suffering from a variety of oral infections. Although these bacteria are not usually considered to be members of the resident oral microflora, they may be present transiently, and they have been isolated from some sites with root surface caries and from some periodontal pockets that fail to respond to conventional therapy.

THE
END

STREPTOCOCCUS

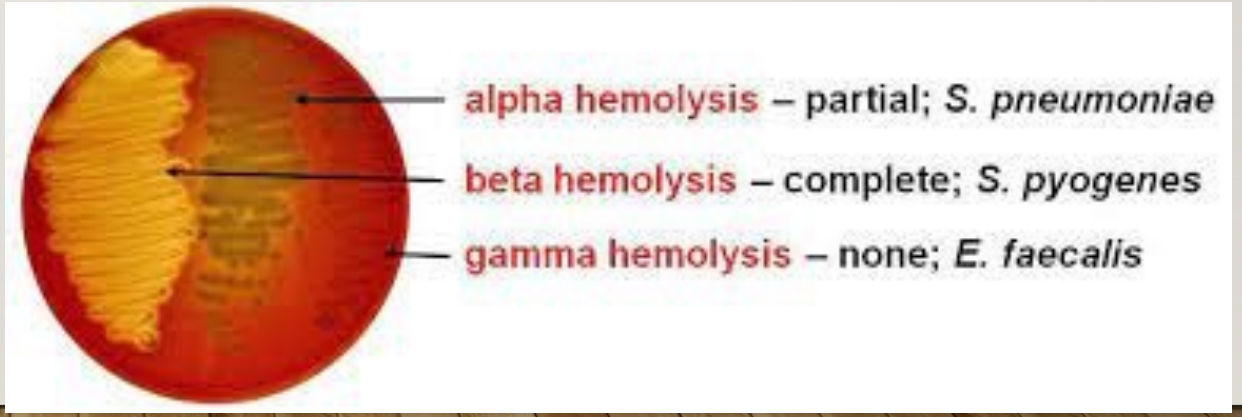
Streptococcus

- Is a genus of Gram-positive *coccus* or spherical bacteria that belongs to the family Streptococcaceae. Cell division in **streptococci** occurs along single axis, so as they grow, and tend to form pairs or chains that may appear bent or twisted. (Contrast with that of staphylococci, which divide along multiple axis, thereby generating irregular, grape-like clusters of cells.)

- Certain Streptococcus species are responsible for many cases of pink eye, meningitis, bacterial pneumonia, endocarditis, erysipelas, and necrotizing fasciitis (the 'flesh-eating' bacterial infections).
- However, many streptococcal species are not pathogenic, and form part of the commensal human microbiota of the mouth, skin, intestine, and upper respiratory tract.

Species of *Streptococcus* are classified based on their hemolytic properties to:

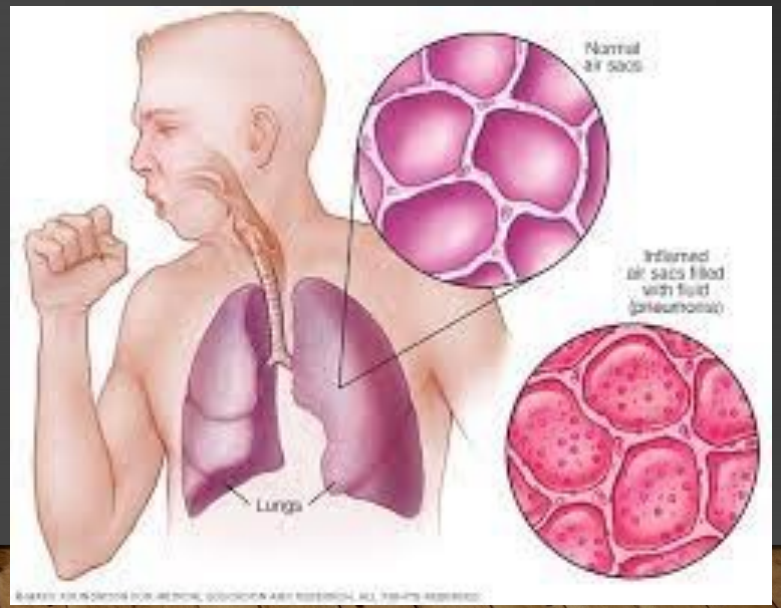
- Alpha-hemolytic: species cause oxidization of iron in hemoglobin molecules within red blood cells, giving it a greenish color on blood agar.
- Beta-hemolytic: species cause complete rupture of red blood cells. On blood agar, this appears as wide areas clear of blood cells surrounding bacterial colonies.
- Gamma-hemolytic: species cause no hemolysis.



- Beta-hemolytic streptococci are further classified by a serotype classification (that is, describing specific carbohydrates present on the bacterial cell wall)
- In the medical setting, the most important groups are the alpha-hemolytic streptococci *S. pneumoniae* and *Streptococcus viridans* group, and the beta-hemolytic streptococci of groups A and B *S. pyogenes* (also known as “group A strep” and “group B strep”).

Pneumococci

- *S. pneumoniae* (sometimes called pneumococcus), is a leading cause of bacterial pneumonia and occasional etiology of otitis media, sinusitis, meningitis, and peritonitis. Inflammation is thought to be the major cause of how pneumococci cause disease.



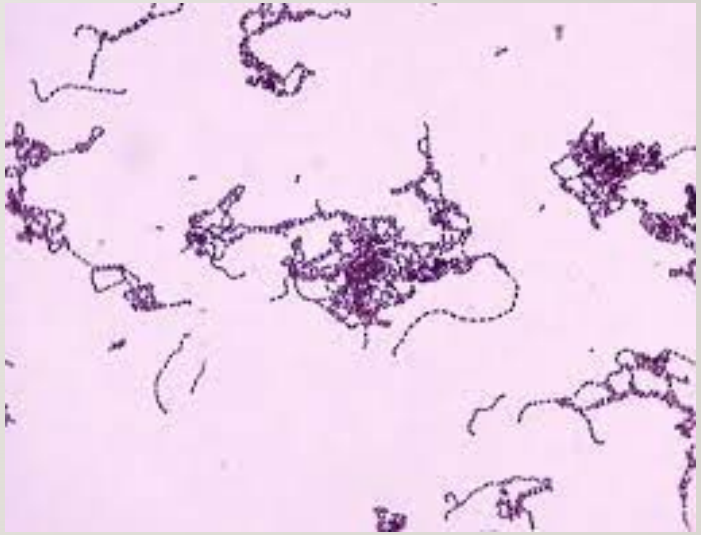
THE VIRIDANS GROUP

- The viridans streptococci are a large group of commensal bacteria that are either alpha-hemolytic, producing a green coloration on blood agar plates , or nonhemolytic.
- Viridans streptococci can be differentiated from *Streptococcus pneumoniae* using an optochin test, as viridans streptococci are optochin-resistant; they also lack either the polysaccharide-based capsule typical of *S. pneumoniae*or the Lancefield antigens of the pyogenic members of the genus

alpha-hemolytic *s. viridans* (right) and beta-hemolytic Group A *s. pyogenes* (left) streptococci growing on blood agar

S. PYOGENES

- ***Streptococcus pyogenes*** is a species of Gram-positive, aerotolerant bacterium .
- These bacteria are extracellular, and made up of non-motile and non-sporing cocci.
- It is clinically important for humans. It is usually pathogenic, but can be part of the skin microbiota.



- *S. pyogenes* (Group A streptococcus) is the causative agent in a wide range of group A streptococcal infections (GAS). These infections may be noninvasive or invasive. The noninvasive infections tend to be more common and less severe. The most common of these infections include streptococcal pharyngitis (strep throat) and impetigo. Scarlet fever is also a noninvasive infection, but has not been as common in recent years.

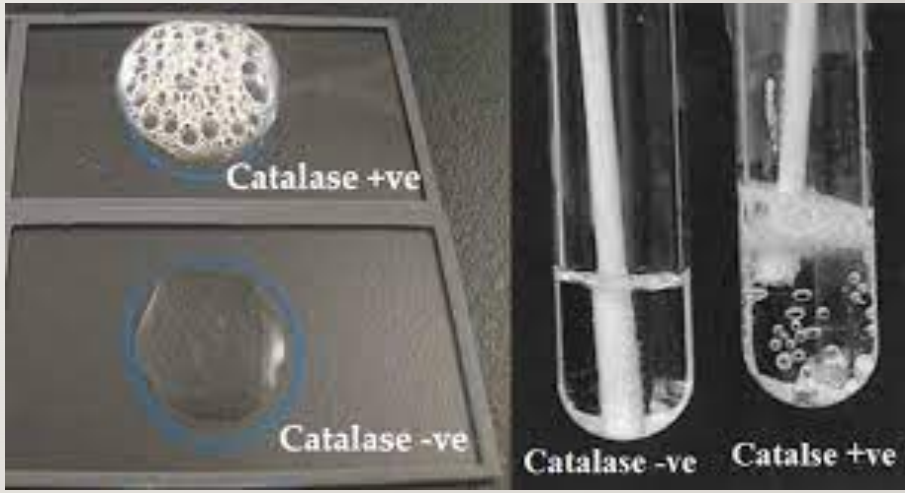
- The invasive infections caused by *S. pyogenes* as one of group A beta-hemolytic streptococci tend to be more severe and less common.

- This occurs when the bacterium is able to infect areas where it is not usually found, such as the blood and the organs.

- The diseases that may be caused include streptococcal toxic shock syndrome, necrotizing fasciitis, pneumonia, and bacteremia. Globally, GAS has been estimated to cause more than 500,000 deaths every year, making it one of the world's leading pathogens.

- Additional complications may be caused by GAS, namely acute rheumatic fever and acute glomerulonephritis.

- *S. pyogenes* can be cultured on fresh blood agar plates. Under ideal conditions, it has an incubation period of 1 to 3 days.
- *S. pyogenes* is catalase negative. This is the main criterion for differentiation between *Staphylococcus* spp. and *Streptococcus* spp. As Staphylococci are catalase positive whereas streptococci are catalase-negative.



- Of healthy individuals, 1% to 5% have throat, vaginal, or rectal carriage. In healthy children, such carriage rate varies from 2% to 17%.
- There are four methods for the transmission of this bacterium: inhalation of respiratory droplets, skin contact, contact with objects, surface, or dust that is contaminated with bacteria or, less commonly, transmission through food.
- The number of pharyngitis cases is higher in children when compared with adults due to exposures in schools, nurseries, and as a consequence of lower host immunity.
- Such cases Streptococcal pharyngitis occurs more frequently from December to April (later winter to early spring) in seasonal countries.

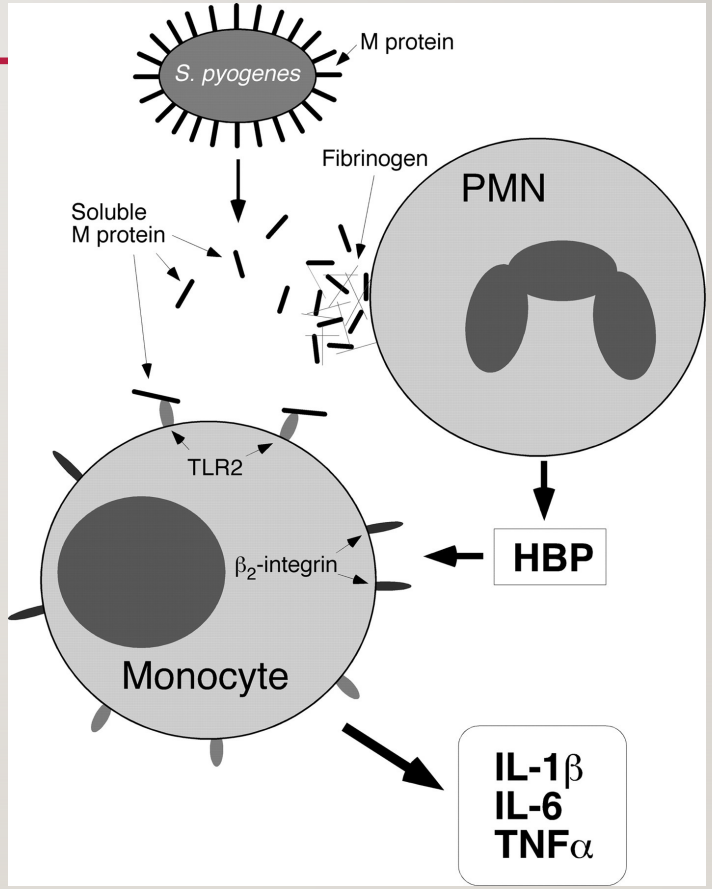
Virulence factors

- ***S. pyogenes*** **has several virulence factors that enable it to attach to host tissues, evade the immune response, and spread by penetrating host tissue layers.**

1- A carbohydrate-based bacterial capsule composed of hyaluronic acid surrounds the bacterium, protecting it from phagocytosis by neutrophils.

Virulence factors

- **2- M protein** also inhibits opsonization by the alternative complement pathway by binding to host complement regulators.
- The M protein is also able to prevent opsonization by binding to fibrinogen.
- However, the M protein is also the weakest point in this pathogen's defence , as antibodies produced by the immune system against M protein target the bacteria for engulfment by phagocytes. M proteins are unique to each strain.



Virulence factors

- **3- Streptolysin O** :it is an exotoxin, one of the bases of the organism's beta-hemolytic property. Streptolysin O causes an immune response and detection of antibodies to it
- 4- Exotoxin A and C: Superantigens secreted by many strains of *S. pyogenes*: This pyogenic exotoxin is responsible for the rash of scarlet fever and many of the symptoms of streptococcal toxic shock syndrome.

Virulence factors

- 5- Exotoxin B : Cysteine protease and the predominant secreted proteins. These exotoxins have multiple actions, including degrading the extracellular matrix, cytokines, complement components, and immunoglobulins. Also called streptopain
- 6-Streptokinase : Enzymatically activates plasminogen, a proteolytic enzyme, into plasmin, which in turn digests fibrin and other proteins

Virulence factors

- 6-Hyaluronidase Hyaluronidase is widely assumed to facilitate the spread of the bacteria through tissues by breaking down hyaluronic acid, an important component of connective tissue.
- 8-Streptodornase: Most strains of *S. pyogenes* secrete up to four different DNases, which are sometimes called streptodornase.

Virulence factors

- 9-C5a peptidase: C5a peptidase cleaves a potent neutrophil chemotaxin called C5a, which is produced by the complement system

- 10-Streptococcal chemokine protease: degrades the chemokine IL-8, which would otherwise attract neutrophils to the site of infection

Disease caused by *S. pyogenes*

- *S. pyogenes* is the cause of many human diseases, ranging from mild superficial skin infections to life-threatening systemic diseases.
- Infections typically begin in the throat or skin. The most striking sign is a strawberry-like rash.
- Examples of mild *S. pyogenes* infections include pharyngitis (strep throat) and localized skin infection (impetigo).
- Erysipelas and cellulitis are characterized by multiplication and lateral spread of *S. pyogenes* in deep layers of the skin.

Disease caused by *S. pyogenes*

- *S. pyogenes* invasion and multiplication in the fascia can lead to necrotizing fasciitis, a life-threatening condition requiring surgery. The bacterium is found in neonatal infections.
- Infections due to certain strains of *S. pyogenes* can be associated with the release of bacterial toxins. Throat infections associated with release of certain toxins lead to scarlet fever. Other toxigenic *S. pyogenes* infections may lead to streptococcal toxic shock syndrome, which can be life-threatening

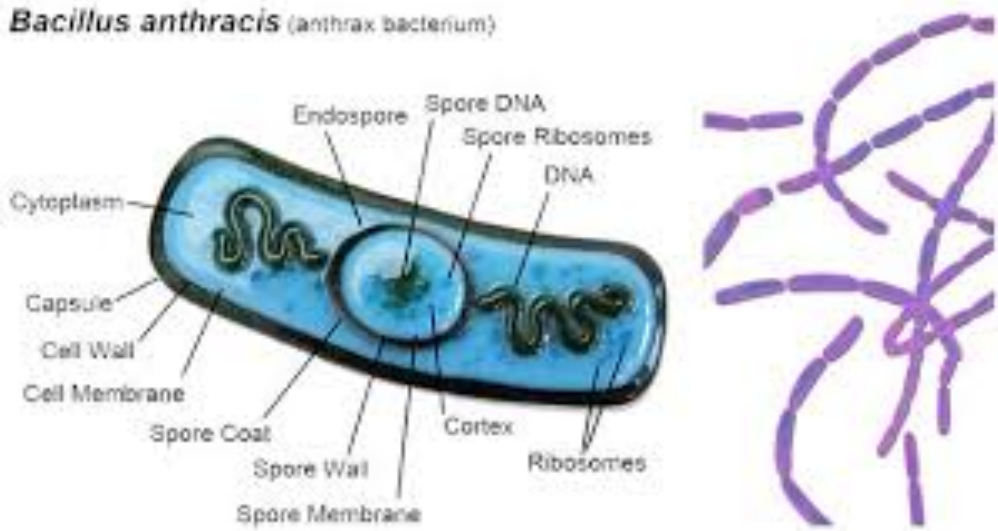
TREATMENT

- This bacterium remains acutely sensitive to penicillin. Failure of treatment with penicillin is generally attributed to other local commensal organisms producing β-lactamase. Certain strains have developed resistance to macrolides, tetracyclines, and clindamycin.

Bacillus and Clostridium

Bacillus anthracis is the agent of anthrax—a common disease of livestock and, occasionally, of humans—and the only obligatepathogen within the genus *Bacillus*. This disease can be classified as a zoonosis, causing infected animals to transmit the disease to humans. [1] *B. anthracis* is a Gram-positive, endospore-forming, rod-shaped bacterium, with a width of 1.0–1.2 µm and a length of 3–5 µm.[1] It can be grown in an ordinary nutrient medium under aerobic or anaerobic conditions

The endospore is a dehydrated cell with thick walls and additional layers that form inside the cell membrane. It can remain inactive for many years, but if it comes into a favorable environment, it begins to grow again. It initially develops inside the rod-shaped form. Features such as the location within the rod, the size and shape of the endospore, and whether or not it causes the wall of the rod to bulge out are characteristic of particular species of *Bacillus*. Depending upon the species, the endospores are round, oval, or occasionally cylindrical. They are highly refractile and contain dipicolinic acid. Electron micrograph sections show they have a thin outer endospore coat, a thick spore cortex, and an inner spore membrane surrounding the endospore contents. The endospores resist heat, drying, and many disinfectants (including 95% ethanol).[3] Because of these attributes, *B. anthracis* endospores are extraordinarily well-suited to use (in powdered and aerosol form) as biological weapons. Such weaponization has been accomplished in the past by at least five state bioweapons programs—those of the United Kingdom, Japan, the United States, Russia, and Iraq—and has been attempted by several others.



B. anthracis are rod-shaped bacteria, approximately 3 to 5 micrometers long and 1 to 1.2 micrometers wide.[5] When grown in culture, they tend to form long chains of bacteria. On agar plates, they form large colonies several millimeters across that are generally white or cream colored.[5] Most *B. anthracis* strains produce a capsule that gives colonies a slimy mucus-like appearance

pXO1 plasmid

The pXO1 plasmid (182 kb) contains the genes that encode for the anthrax toxin components: *pag* (protective antigen, PA), *lef* (lethal factor, LF), and *cya* (edema factor, EF). These factors are contained within a 44.8-kb pathogenicity island (PAI). The lethal toxin is a combination of PA with LF and the edema toxin is a combination of PA with EF. The PAI also contains genes which encode a transcriptional activator AtxA and the repressor PagR, both of which regulate the expression of the anthrax toxin genes.[7]

pXO2 plasmid

pXO2 encodes a five-gene operon (*capBCADE*) which synthesizes a poly-γ-D-glutamic acid (polyglutamate) capsule. This capsule allows *B. anthracis* to evade the host immune system by protecting itself from phagocytosis. Expression of the capsule operon is activated by the transcriptional regulators AcpA and AcpB, located in the pXO2 pathogenicity island (35 kb). AcpA and AcpB expression are under the control of AtxA from pXO1

Pathogenesis

B. anthracis possesses an antiphagocytic capsule essential for full virulence. The organism also produces three plasmid-coded exotoxins: edema factor, a calmodulin-dependent adenylate cyclase that causes elevation of intracellular **Cyclic adenosine monophosphate** and is responsible for the severe edema usually seen in *B. anthracis* infections, lethal toxin which is responsible for causing tissue necrosis, and protective antigen, so named because of its use in producing protective anthrax vaccines, which mediates cell entry of edema factor and lethal toxin.

The symptoms in anthrax depend on the type of infection and can take anywhere from 1 day to more than 2 months to appear. All types of anthrax have the potential, if untreated, to spread throughout the body and cause severe illness and even death.[19]

Four forms of human anthrax disease are recognized based on their portal of entry.

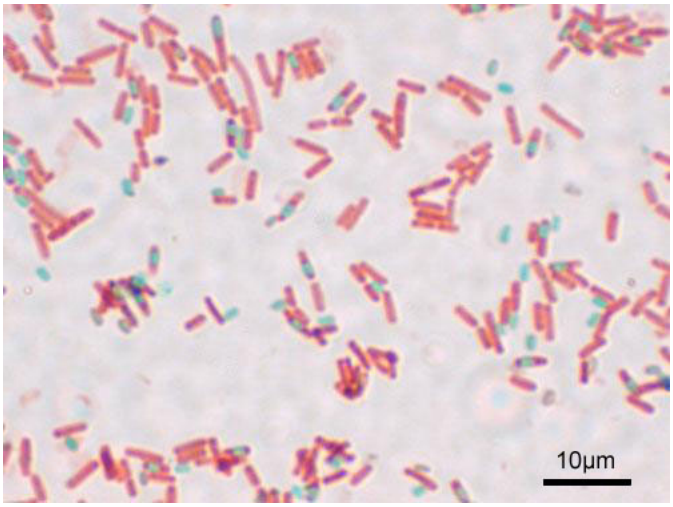
- Cutaneous, the most common form (95%), causes a localized, inflammatory, black, necrotic lesion (eschar). Most often the sore will appear on the face, neck, arms, or hands. Development can occur within 1-7 days after exposure.
- Inhalation, a rare but highly fatal form, is characterized by flu-like symptoms, chest discomfort, diaphoresis, and body aches.[19] Development occurs usually a week after exposure, but can take up to two months.
- Gastrointestinal, a rare but also fatal (causes death to 25%) type, results from ingestion of spores. Symptoms include: fever and chills, swelling of neck, painful swallowing, hoarseness, nausea and vomiting (especially bloody vomiting), diarrhea, flushing and red eyes, and swelling of abdomen.[19] Symptoms can develop within 1-7 days
- Injection, symptoms are similar to those of cutaneous anthrax, but injection anthrax can spread throughout the body faster and can be harder to recognize and treat compared to cutaneous anthrax.[19]. Symptoms include, fever, chills, a group of small bumps or blisters that may itch, appearing where the drug was injected. A painless sore with a black center that appears after the blisters or bumps. Swelling around the sore. Abscesses deep under

the skin or in the muscle where the drug was injected. This type of entry has never been found in the US.

- 
Prevention and treatment

A number of anthrax vaccines have been developed for preventive use in livestock and humans. Anthrax vaccine adsorbed (AVA) may protect against cutaneous and inhalation anthrax. However, this vaccine is only used for at-risk adults before exposure to anthrax and has not been approved for use after exposure.[20] Infections with *B. anthracis* can be treated with β-lactam antibiotics such as penicillin, and others which are active against Gram-positive bacteria.[21] Penicillin-resistant *B. anthracis* can be treated with fluoroquinolones such as ciprofloxacin or tetracycline antibiotics such as doxycycline.

Bacillus subtilis, known also as the **hay bacillus** or **grass bacillus**, is a Gram-positive, catalase-positive bacterium, found in soil and the gastrointestinal tract of ruminants and humans. A member of the genus *Bacillus*, *B. subtilis* is rod-shaped, and can form a tough, protective endospore, allowing it to tolerate extreme environmental conditions. *B. subtilis* has historically been classified as an obligate aerobe, though evidence exists that it is a facultative anaerobe. *B. subtilis* is considered the best studied Gram-positive bacterium and a model organism to study bacterial chromosome replication and cell differentiation. It is one of the bacterial champions in secreted enzyme production and used on an industrial scale by biotechnology companies.



Clostridium perfringens (formerly known as *C. welchii*, or *Bacillus welchii*) is a Gram-positive, rod-shaped, anaerobic, spore-forming pathogenic bacterium of the genus *Clostridium*.[1][2] *C. perfringens* is ever-present in nature and can be found as a normal component of decaying vegetation, marine sediment, the intestinal tract of humans and other vertebrates, insects, and soil. It has the shortest reported generation time of any organism at 6.3 minutes in thioglycolate medium

Infections due to *C. perfringens* show evidence of tissue necrosis, bacteremia, emphysematous cholecystitis, and gas gangrene, also known as clostridial myonecrosis. The specific name *perfringens* is derived from the Latin *per* (meaning "through") and *frango* ("burst"), referring to the disruption of tissue that occurs during gas gangrene.[6] The toxin involved in gas gangrene is α-toxin, which inserts into the plasma membrane of cells, producing gaps in the membrane that disrupt normal cellular function. *C. perfringens* can participate in polymicrobial anaerobic infections. It is commonly encountered in infectionsas a component of the normal flora. In this case, its role in disease is minor.

Food poisoning

Food poisoning in humans is caused by type A strains able to produce the *CPE* (for *Clostridium perfringens* enterotoxin).[9] The *CPE* is a polypeptide of 35.5 kDa that accumulates in the beginning of the sporulation and is excreted to the media when it lysates at the end of the sporulation. It is coded by the *cpe* gene, present in less than the 5% of the type A strains, and it can be located in the chromosome or in an external plasmid

The *C. perfringens* enterotoxin (CPE) mediating the disease is heat-labile (inactivated at 74 °C (165 °F)). It can be detected in contaminated food (if not heated properly), and feces.[12] Incubation time is between 6 and 24 (commonly 10–12) hours after ingestion of contaminated food.

Since *C. perfringens* forms spores that can withstand cooking temperatures, if cooked food is let stand for long enough, germination can ensue and infective bacterial colonies develop. Symptoms typically include abdominal cramping, diarrhea, vomiting, and fever.[13] The whole course usually resolves within 24 hours, but can last up to 2 weeks in older or infirm hosts.

C. perfringens poisoning can also lead to another disease known as enteritis necroticans or clostridial necrotizing enteritis, (also known as pigbel); this is caused by *C. perfringens* type C. However, this infection is often fatal. Large numbers of *C. perfringens* grow in the intestines, and secrete exotoxin. This exotoxin causes necrosis of the intestines, varying levels

of hemorrhaging, and perforation of the intestine. Inflammation usually occurs in sections of the jejunum, midsection of the small intestine. This disease eventually leads to septic shock and death. This particular disease is rare in the United States; typically, it occurs in populations with a higher risk.

Infection

C. perfringens is the most common bacterial agent for gas gangrene. Some symptoms include blisters, tachycardia, swelling, and jaundice.[15]

A strain of *C. perfringens* might be implicated in multiple sclerosis (MS) nascent (Pattern III) lesions.[16] Tests in mice found that a toxin made by a rare strain of *C. perfringens* caused MS-like damage in the brain, and earlier work had identified this strain of *C. perfringens* in a human with MS.[17] MS patients were found to be 10 times more immune-reactive to the epsilon toxin than healthy people.[18]

Treatment[edit]

The most important aspect of treatment is prompt and extensive surgical debridement of the involved area and excision of all devitalized tissue, in which the organisms are prone to grow. Administration of antimicrobial drugs, particularly penicillin, is begun at the same time. Hyperbaric oxygen may be of help in the medical management of clostridial tissue infections. It is said to "detoxify" patients rapidly.[19]

Diagnosis

C. perfringens can be diagnosed by Nagler's reaction, in which the suspect organism is cultured on an egg yolk media plate. One side of the plate contains anti-alpha-toxin, while the other side does not. A streak of suspect organism is placed through both sides. An area of turbidity will form around the side that does not have the anti-alpha-toxin, indicating uninhibited lecithinase activity. In addition, laboratories can diagnose the bacteria by determining the number of bacteria in the feces. Within the 48 hours from when the disease began, if the individual has more than 106 spores of the bacteria per gram of stool, then the illness is diagnosed as *C. perfringens* food poisoning.[14] Other tests/reactions: Catalase: Negative, Spot indole: Negative [20], Lecithinase: Positive, Lipase: Negative, Litmus Milk: Stormy Fermentation, Reverse CAMP plate: Positive, Gas Liquid Chromatography products: (Acetic, Butyric and Lactic Acids).

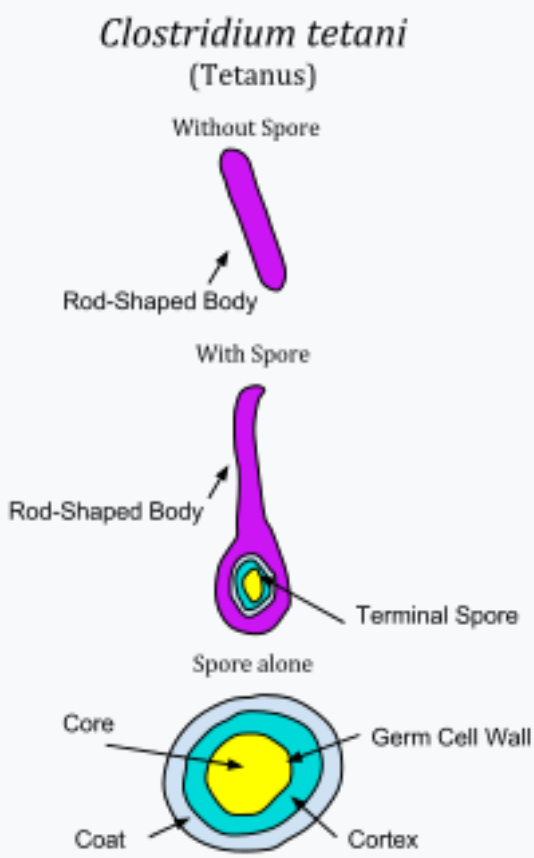
Typically, the symptoms of *C. perfingens* poisoning are used to diagnose it. However, diagnosis can be made using a stool culture test, in which the feces are tested for toxins produced by the bacteria.[21]

Prevention

The growth of *C. perfringens* spores can be prevented by most importantly cooking food, especially beef and poultry, thoroughly, to the recommended temperatures. Leftover food should be refrigerated to a temperature below 40 °F (4 °C) within two hours of preparation. Large pots of food such as soup or stew with meats should be divided into small quantities and covered for refrigeration. Leftovers should be reheated to at least 165 °F (74 °C) before serving. A rule of thumb is that if the food tastes, smells, or looks different from what it is supposed to, then the food should be avoided. Even if it looks safe, a food that has been out for a long time can also be dangerous to eat

Clostridium tetani is a common soil bacterium and the causative agent of tetanus. When growing in soil, *C. tetani* is rod-shapedand up to 2.5 µm long. However, when forming spores, *C. tetani* becomes substantially enlarged at one end, resembling a tennis racket or drumstick. *C. tetani* spores are extremely hardy and can be found globally in soil or in the gastrointestinal tract of animals. If inoculated into a wound, *C. tetani* can grow and produce a potent toxin, tetanospasmin, which interferes with motor neurons, causing tetanus. The toxin's action can be prevented with tetanus toxoid vaccines, which are often administered to children worldwide.

Characteristics



A diagram of *C. tetani* showing the bacterium alone, with a spore being produced, and the spore alone

C. tetani is a rod-shaped, Gram-positive bacterium, typically up to 0.5 µm wide and 2.5 µm long.[1] It is motile by way of various flagella that surround its body.[1] *C. tetani* cannot grow in the presence of oxygen.[1] It grows best at temperatures ranging from 33 to 37°C.[1]

Upon exposure to various conditions, *C. tetani* can shed its flagella and form a spore.[1] Each cell can form a single spore, generally at one end of the cell, giving the cell a distinctive drumstick shape.[1] *C. tetani* spores are extremely hardy and are resistant to heat, various antiseptics, and boiling for several minutes.[2] The spores are long-lived and are distributed worldwide in soils as well as in the intestines of various livestock and companion animals

Role in disease

While *C. tetani* is frequently benign in the soil or in the intestinal tracts of animals, it can sometimes cause the severe disease tetanus. Disease generally begins with spores entering the body through a wound.[5] In deep wounds, such as those from a puncture or contaminated needle injection the combination of tissue death and limited exposure to surface air can result in a very low-oxygen environment, allowing *C. tetani* spores to germinate and grow.[2] As *C. tetani* grows at the wound site, it releases the toxins tetanolysin and tetanospasmin as cells lyse.[1] The function of tetanolysin is unclear, although it may help *C. tetani* to establish infection within a wound.[6][1] Tetanospasmin ("tetanus toxin") is one of the most potent toxins known, with an estimated lethal dose less than 2.5 nanograms per kilogram of body weight, and is responsible for the symptoms of tetanus.[6][1]Tetanospasmin spreads via the lymphatic system and bloodstream throughout the body, where it is taken up into various parts of the nervous system. This leads to the widespread activation of motor neurons and spasming of muscles throughout the body.[6] These muscle spasms generally begin at the top of the body and move down, beginning about 8 days after infection with lockjaw, followed by spasms of the abdominal muscles and the limbs.[5][6] Muscle spasms continue for several weeks.

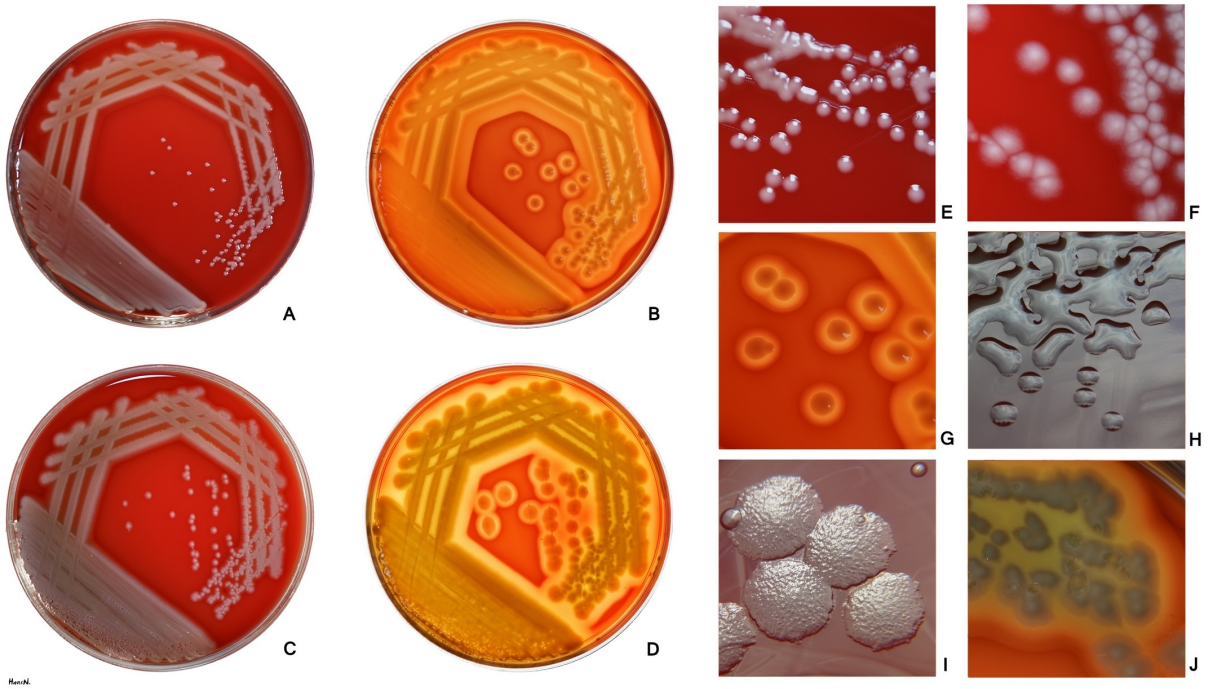
Treatment and prevention

C. tetani is susceptible to a number of antibiotics, including chloramphenicol, clindamycin, erythromycin, penicillin G, and tetracycline.[3] However, the usefulness of treating *C. tetani* infections with antibiotics remains unclear.[1] Instead, tetanus is often treated with tetanus immune globulin to bind up circulating tetanospasmin.[6] Additionally, benzodiazepines or muscle relaxants may be given to reduce the effects of the muscle spasms.[1]

Damage from *C. tetani* infection is generally prevented by administration of a tetanus vaccine consisting of tetanospasmin inactivated by formaldehyde, called tetanus toxoid

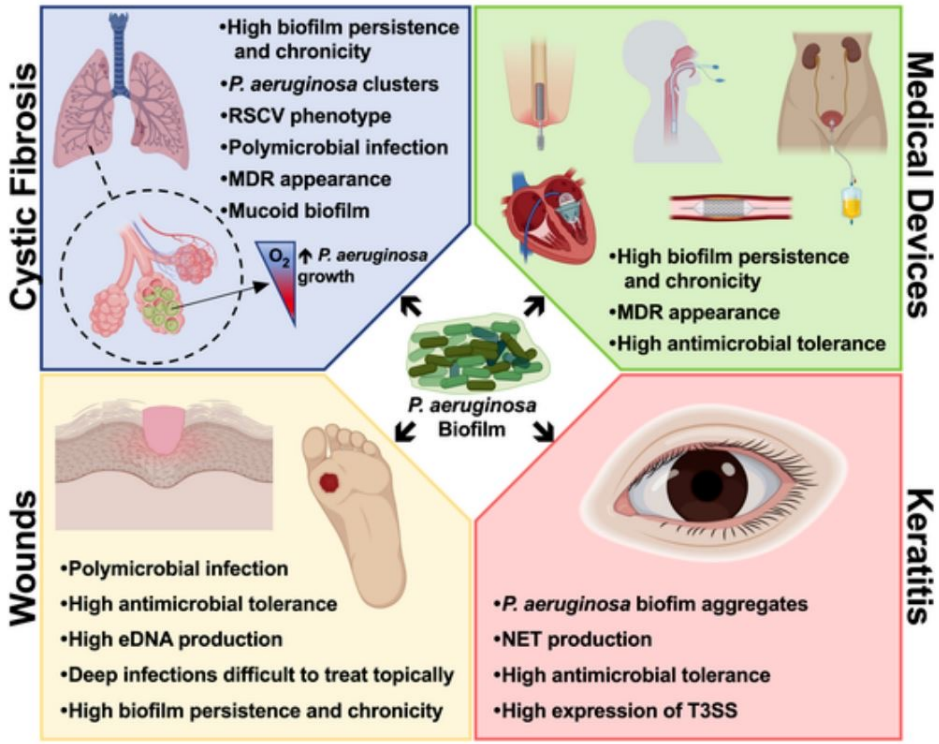
Pseudomonas aeruginosa

- ***Pseudomonas aeruginosa*** is a common encapsulated, Gram-negative, strict aerobic (although can grow anaerobically in the presence of nitrate), Rod-shaped bacterium that can cause disease in plants and animals, including humans.



Its medical importance is attributed to:

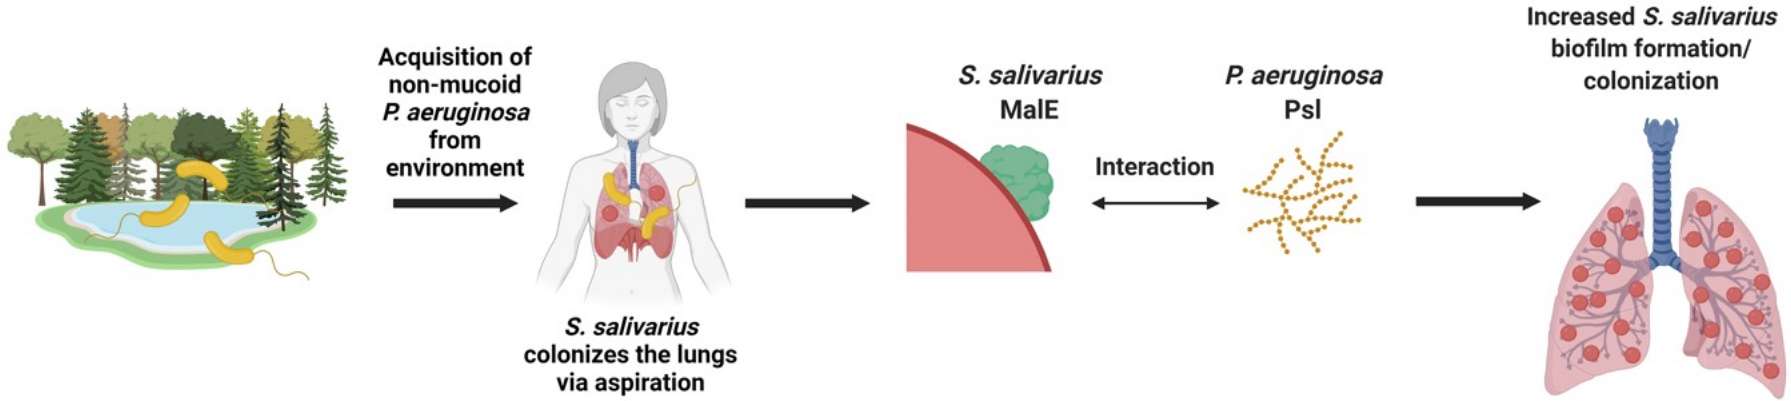
- *P. aeruginosa* is a multidrug resistant pathogen due to its advanced antibiotic resistance mechanisms.
- its association with serious illnesses – hospital-acquired infections such as ventilator-associated pneumonia and various sepsis syndromes.
- Infections are Nosocomial catheterized patients, respiratory tract infections (cystic fibrosis), urinary tract infections, wound infections, and eye infection (keratitis).



- The organism is considered opportunistic as serious infection often occurs during existing diseases
- It generally affects the immunocompromised but can also infect the immunocompetent. The symptoms of such infections are generalized inflammation and sepsis.
- If such colonizations occur in critical body organs, such as the lungs, the urinary tract, and kidneys, the results could be fatal.
- Treatment of *P. aeruginosa* infections can be difficult due to its natural resistance to antibiotics.

- Treatment of *P. aeruginosa* infections can be difficult due to its natural resistance to antibiotics.
- *However, P. aeruginosa* is not extremely virulent in comparison with other major pathogenic bacterial species – for example the Gram-positive *Staphylococcus aureus* and *Streptococcus pyogenes*
- *P. aeruginosa* is capable of extensive colonization, and can aggregate into enduring biofilms.

- It is citrate, catalase, and oxidase positive. It is found in soil, water, skin flora, and most man-made environments throughout the world.
- It thrives not only in normal atmospheres, but also in low-oxygen atmospheres, thus has colonized many natural and artificial environments.



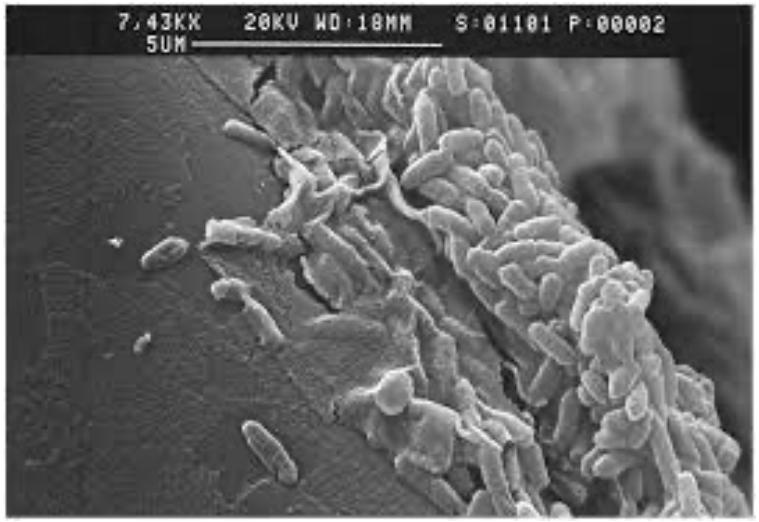
Toxins

- *P. aeruginosa* uses the virulence factor exotoxin A to inactivate eukaryotic elongation factor 2 in the host cell, much as the diphtheria toxin does. Without elongation factor 2, eukaryotic cells cannot synthesize proteins and necrotise.

- *P. aeruginosa* uses an exoenzyme U (ExoU), which degrades the plasma membrane of eukaryotic cells, leading to lysis.

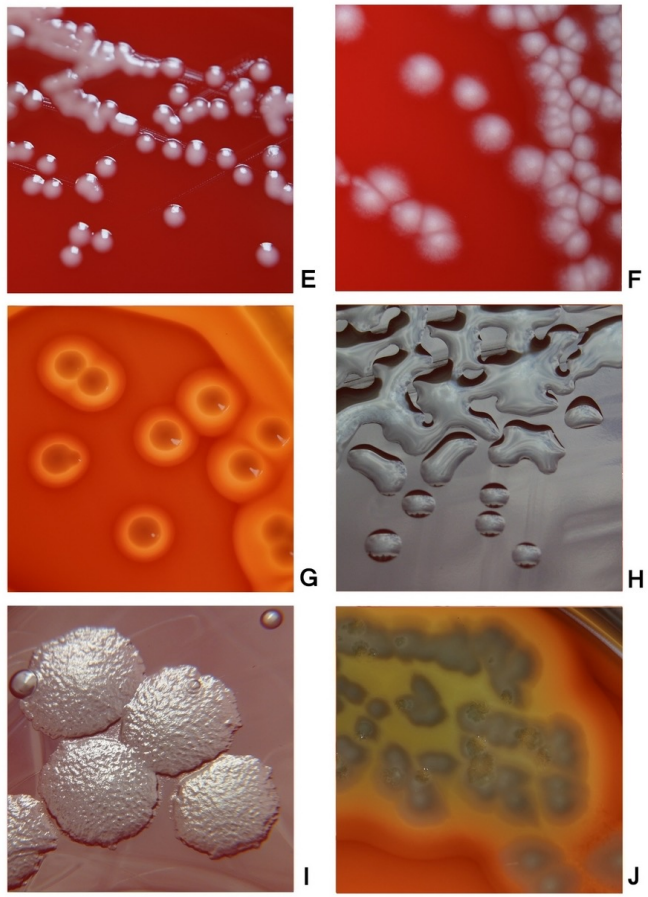
Biofilms formation

- Biofilms of *P. aeruginosa* can cause chronic opportunistic infections, which are a serious problem for medical care especially for immunocompromised patients and the elderly. They often cannot be treated effectively with traditional antibiotic therapy.
- Biofilms seem to protect these bacteria from adverse environmental factors.
- Researchers consider it important to learn more about the molecular mechanisms that cause the switch from planktonic growth to a biofilm phenotype.



Diagnosis

- Depending on the nature of infection, an appropriate specimen is collected and sent to a bacteriology laboratory for identification.
- As with most bacteriological specimens, a Gram stain is performed, which may show Gram-negative rods and/or white blood cells.
- *P. aeruginosa* produces colonies with a characteristic "grape-like" on bacteriological media. In mixed cultures, it can be isolated as clear colonies on MacConkey agar, it does not ferment lactose, which will test positive for oxidase.



- Confirmatory tests include production of the blue-green pigment pyocyanin on cetrimide agar .
- A Trible sugar iron slant is often used to distinguish nonfermenting *Pseudomonas* species from enteric pathogens in faecal specimens.
- When *P. aeruginosa* is isolated from a normally sterile site (blood, bone, deep collections), it is generally considered dangerous and almost always requires treatment.

Treatment

- Many *P. aeruginosa* isolates are resistant to a large range of antibiotics and may demonstrate additional resistance after unsuccessful treatment.
- It should usually be possible to guide treatment according to laboratory sensitivities, rather than choosing an antibiotic empirically.

- Due to widespread resistance to many common first-line antibiotics, carbapenems, polymyxins, and more recently tigecycline were considered to be the drugs of choice.
- however, resistance to these drugs has also been reported. Despite this, they are still being used in areas where resistance has not yet been reported.
- Use of β-lactamase inhibitors such as **sulbactam (** beta-lactamase inhibitors) has been advised in combination with antibiotics to enhance antimicrobial action even in the presence of a certain level of resistance.

- *P. aeruginosa* low antibiotic susceptibility is attributable to a concerted action of multidrug efflux pumps with chromosomally encoded antibiotic resistance genes
- Efflux pumps are capable of moving a variety of different toxic compounds out of cells, such as antibiotics,
- Moreover, *P. aeruginosa* have low permeability of the bacterial cellular envelopes
- In addition to this intrinsic resistance, *P. aeruginosa* easily develops acquired resistance either by mutation in chromosomally encoded genes or by the horizontal gene transfer of antibiotic resistance determinants.
- Hypermutation favours the selection of mutation-driven antibiotic resistance in *P. aeruginosa* strains producing chronic infections.

Prevention

- Probiotic prophylaxis may prevent colonization and delay onset of *Pseudomonas* infection in an ICU setting. Immunoprophylaxis against *Pseudomonas* is being investigated. The risk of contracting *P. aeruginosa* can be reduced by avoiding pools, hot tubs, and other bodies of standing water, as well as individual hygiene.

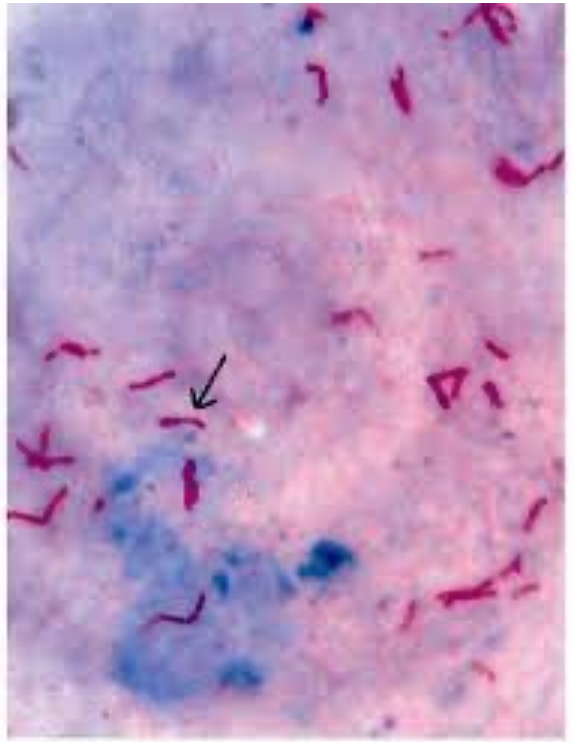
Mycobacterium tuberculosis

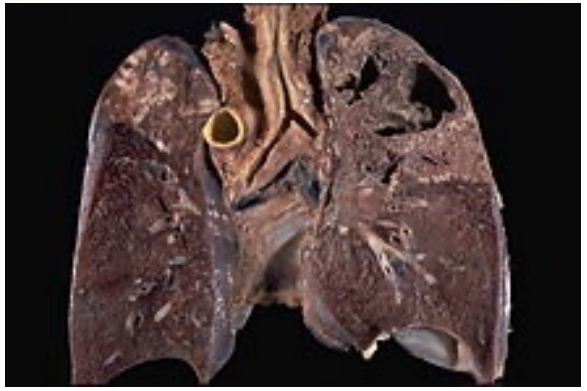
Mycobacterium tuberculosis is a species of pathogenic bacteria in the family Mycobacteriaceae and the causative agent of tuberculosis.

M. tuberculosis has an unusual, waxy coating on its cell surface primarily due to the presence of mycolic acid (Mycolic acids are **long fatty acids found in the cell walls of the bacteria)**

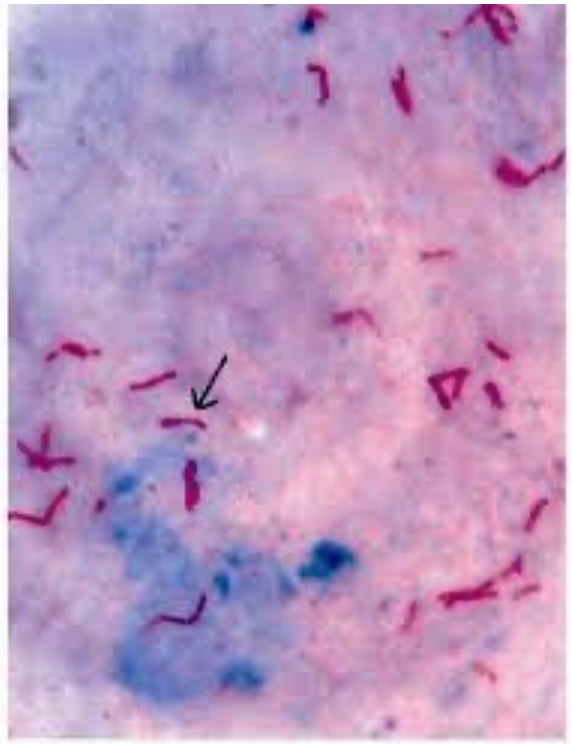
This coating makes the cells impervious to Gram staining, and as a result, *M. tuberculosis* can appear weakly Gram-positive.

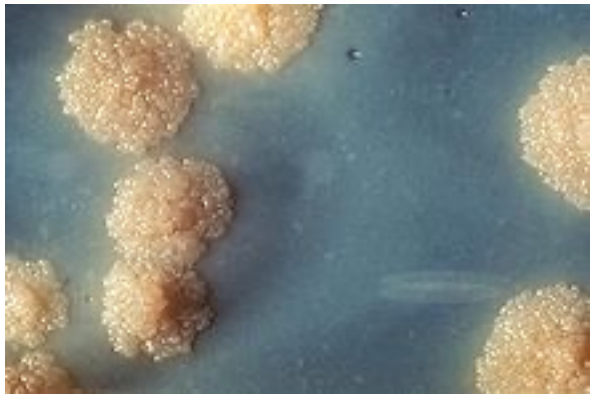
Acid-fast stains such as Ziehl–Neelsen, or fluorescent stains such as auramine are used instead to identify *M. tuberculosis* with a microscope.



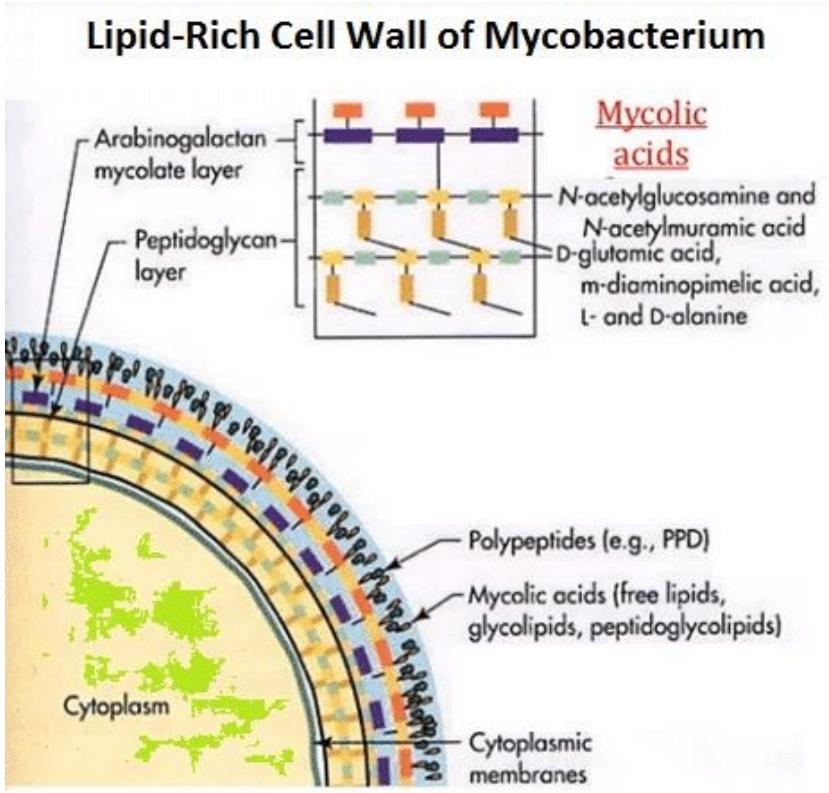


- The physiology of *M. tuberculosis* is highly aerobic and requires high levels of oxygen.
- Primarily a pathogen of the mammalian respiratory system, it infects the lungs.
- The most frequently used diagnostic methods for tuberculosis are the tuberculin skin test, acid-fast stain, culture, and polymerase chain reaction





- *M. tuberculosis* divides every 18–24 hours. This is extremely slow compared with other bacteria, which tend to have division times measured in minutes (*Escherichia coli* can divide roughly every 20 minutes).
- It is a small bacillus that can withstand weak disinfectants and can survive in a dry state for weeks.
- Its unusual cell wall is rich with mycolic acid, is likely responsible for its resistance to desiccation and is a key virulence factor

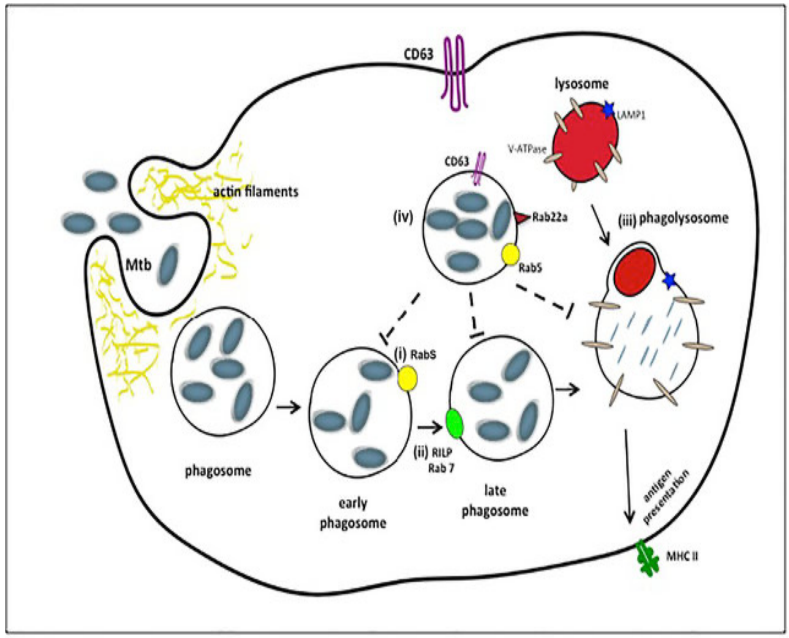


Culture

- *M. tuberculosis* can be grown in the laboratory. Compared to other commonly studied bacteria, *M. tuberculosis* has a remarkably slow growth rate, doubling roughly once per day.
- Commonly used media include liquids such as Middlebrook 7H9 or 7H12, egg-based solid media such as Lowenstein-Jensen, and solid agar-based such as Middlebrook 7H11 or 7H10.
- Visible colonies require several weeks to grow on agar plates. It is distinguished from other mycobacteria by its production of catalase and niacin. Other tests to confirm its identity include PCR or gene probes .

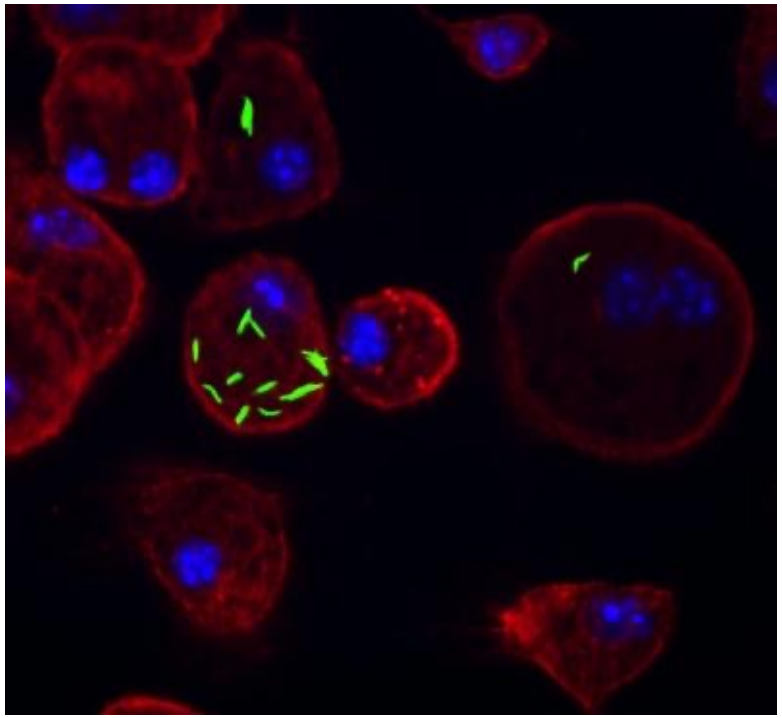
Pathophysiology

- Humans are the only known reservoirs of *M. tuberculosis*.
- major spread is through air droplets from a person who has the disease either coughing, sneezing or speaking.
- When in the lungs, *M. tuberculosis* is phagocytosed by alveolar macrophages, but they are unable to kill and digest the bacterium. Its cell wall inhibits the fusion of the phagosome with the lysosomes.
- In addition, production of the diterpene isotuberculosinol prevents maturation of the phagosome.
- Mutations in genes involved in the specific biosynthetic pathways resulting in normal development of the phagosome and reduction of mycobacterial infection.

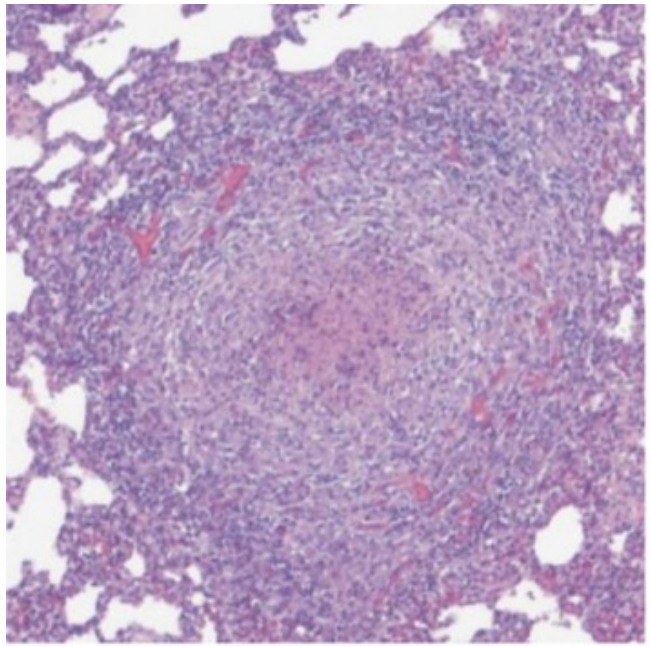


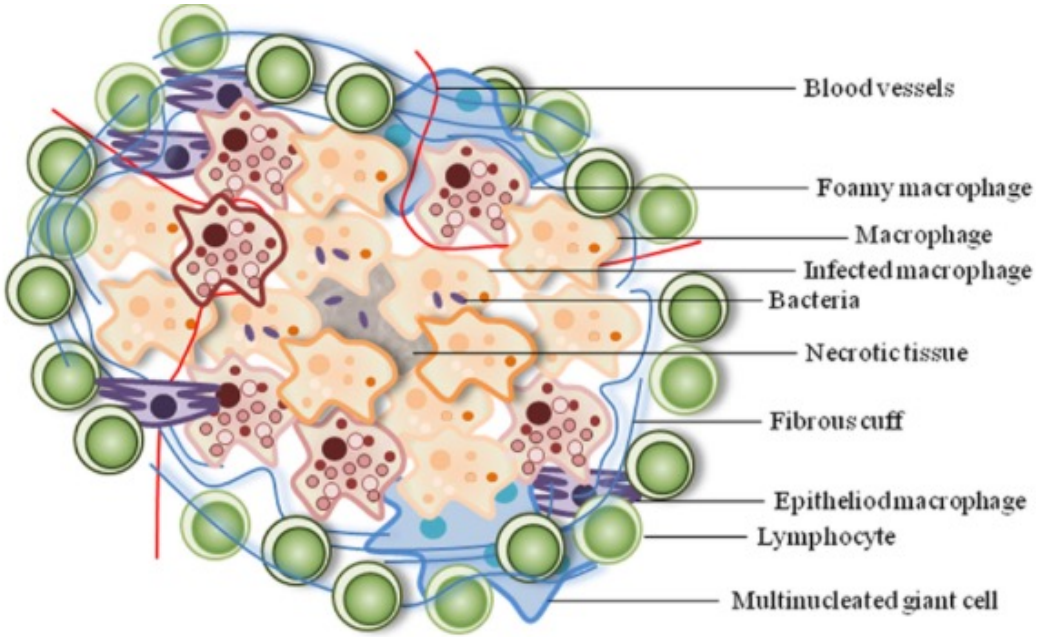
- In M.tuberculosis infection, the PPM1A protein levels were found to be upregulated , as PPM1A inhibits the intrinsic and extrinsic apoptotic pathways.

- As a result of having apoptosis being suppressed, it provides *M. tuberculosis* with a safe replicative niche, and so the bacteria are able to maintain a latent state for a prolonged time.

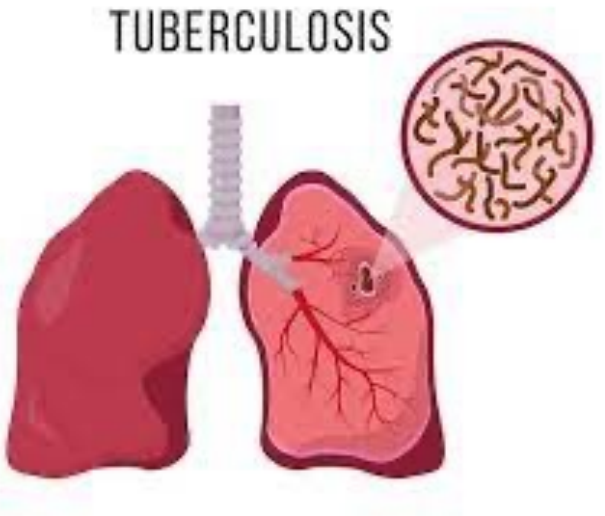


- Granulomas, organized aggregates of immune cells, are a hallmark feature of tuberculosis infection.
- Granulomas play dual roles during infection: they regulate the immune response and minimize tissue damage, but also can aid in the expansion of infection.



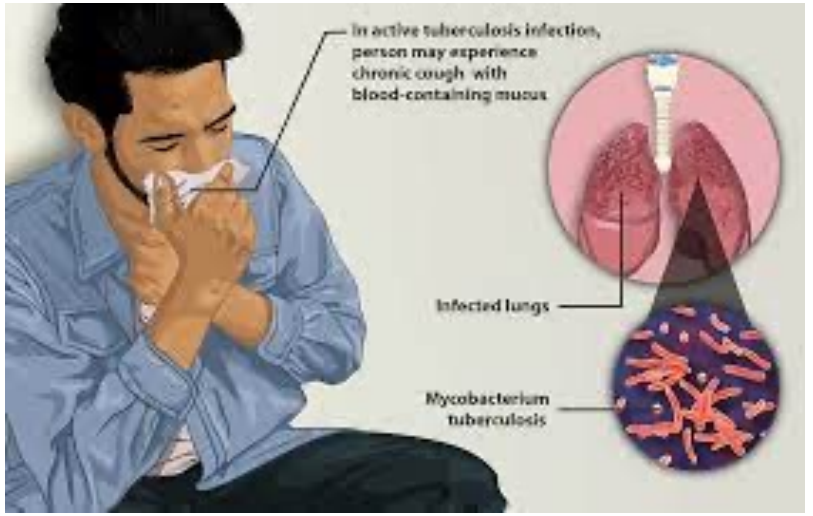


- one of virulence factors is cord factor (is a glycolipid molecule found in the cell wall of *Mycobacterium tuberculosis*), which serves to increase survival within its host.
- In addition, pre-existing first-line TB drugs such as rifampicin and streptomycin have decreased efficiency in clearing intracellular *M. tuberculosis* due to not being able to effectively penetrate the macrophage niche.



Symptoms

- Symptoms of *M. tuberculosis* include coughing that lasts for more than three weeks, hemoptysis (cough with blood or bloody mucus), chest pain when breathing or coughing, weight loss, fatigue, fever, night sweats, chills, and loss of appetite.
- *M. tuberculosis* also has the potential of spreading to other parts of the body.
- This can cause blood in urine if the kidneys are affected, and back pain if the spine is affected



Antibiotic resistance

- *M. tuberculosis* is a clonal organism and does not exchange DNA via horizontal gene transfer
- the emergence and spread of antibiotic resistance in *M. tuberculosis* poses an increasing threat to global public health
- Multidrug-resistant Tuberculosis (MDR-TB) is characterised by resistance to at least the two front-line drugs isoniazid and rifampin
- Isoniazid and rifampin resistance are tightly linked, with 78% of the reported rifampin-resistant TB cases in 2019 being resistant to isoniazid as well
- Rifampin-resistance is primarily due to resistance-conferring mutations in the rifampin-resistance determining region (RRDR) within the rpoB gene

- Isoniazid function occurs through the inhibition of mycolic acid synthesis by its binding to a protein encoded by the *inhA* gene.
- As a result, isoniazid resistance is primarily due to mutations within *inhA* gene.
- MDR in *M. tuberculosis* becomes increasingly common, and led to the emergence of extensively drug resistant (XDR-) TB which considered as a public health crises.
- XDR-TB is characterised by resistance to both rifampin and Isoniazid, as well second-line fluoroquinolones and at least one additional front-line drug.

Treatment

- Person with TB disease will probably be treated with a combination of antibacterial medications for a period of six to 12 months.
- The most common treatment for active TB is isoniazid in combination with three other drugs—rifampin, pyrazinamide and ethambutol.
- Patient may begin to feel better only a few weeks after starting to take the drugs but treating TB takes much longer than other bacterial infections.

- Patient must continue taking his medication as prescribed for the entire time his doctor indicates or he could get sick again, have a harder time fighting the disease in the future and spread the disease to others.
- Not completing the entire course of medication could also contribute to drug-resistant TB which takes much longer, 20 to 30 months to complete.

Vaccine

- The BCG vaccine (bacille Calmette-Guerin), which was derived from *M. bovis,* while effective against childhood and severe forms of tuberculosis.
- However It has limited success in preventing the most common form of the disease today

Immunity

The term immunity refers to the general ability of a host to resist a particular infection or disease.

Immunology is the science that is concerned with immune responses to foreign challenge and how these responses are used to resist infection. It includes the distinction between “self” and “non-self” and all the biological, chemical, and physical aspects of the immune response. There are two fundamentally different types of immune responses to an invading microorganism and/or foreign material.

Cells of the Immune System

The cells responsible for both nonspecific and specific immunity are the leukocytes. All leukocytes originate from stem cells in the fetal liver and in the bone marrow of the animal host. stem cells have not yet committed to differentiating into one specific cell type. When they migrate to other body sites, some differentiate into hematopoietic stem cells that are destined to become blood cells. When stimulated to undergo further development, some leukocytes become residents within tissues, where they respond to local trauma. These cells may sound the alarm that signals invasion by foreign organisms. Other leukocytes circulate in body fluids and are recruited to the sites of infection after the alarm has been raised. The average adult has approximately 7,400 leukocytes per cubic millimeter of blood

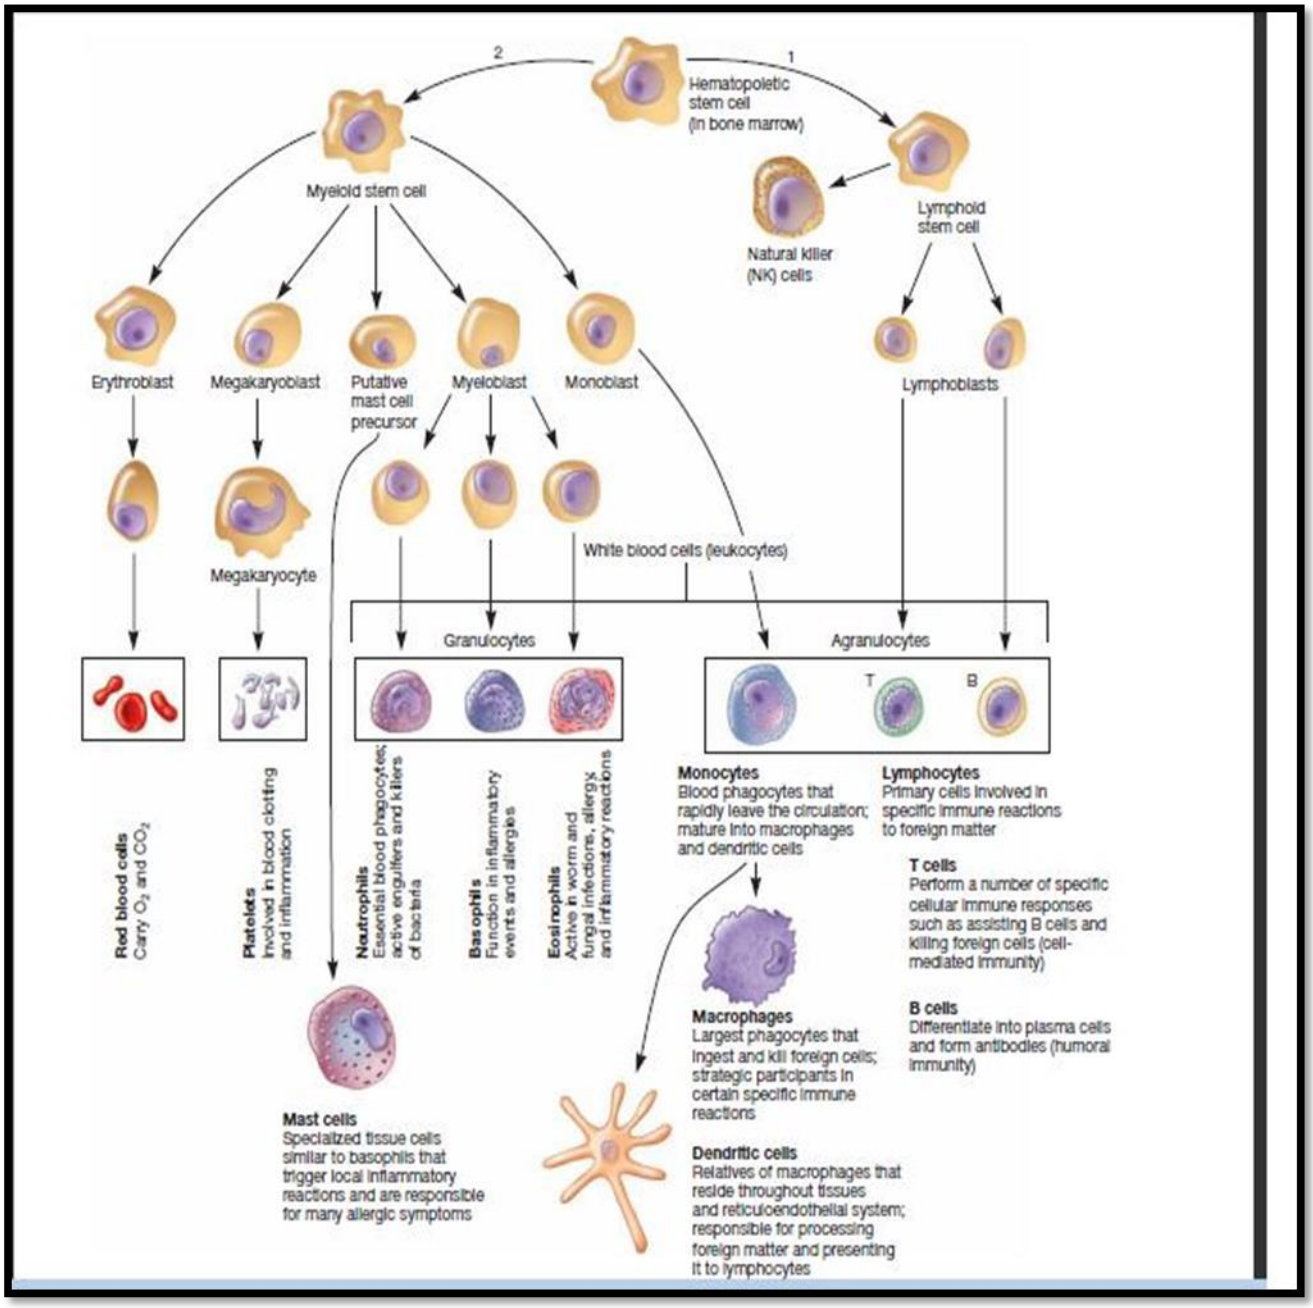
Normal Adult Blood Count

Cell Type	Cells/mm^3	Percent WBC
Red blood cells	5,000,000	
Platelets	250,000	
White blood cells	7,400	100
Neutrophils	4,320	60
Lymphocytes	2,160	30
Monocytes	430	6
Eosinophils	215	3
Basophils	70	1

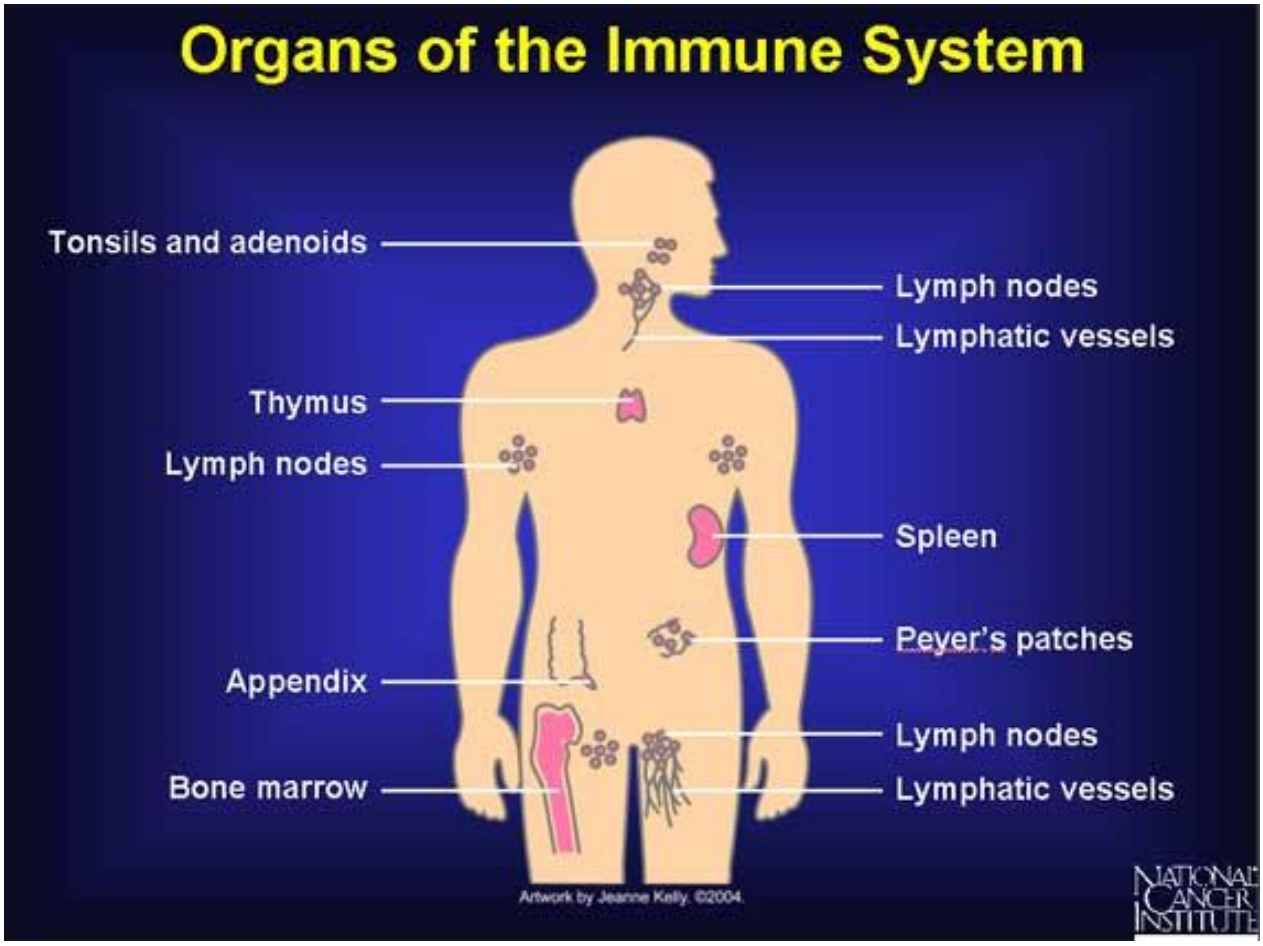
This average value shifts substantially during an immune response. In defending the host against pathogenic microorganisms, leukocytes cooperate with each other first to recognize the pathogen as an invader and then to destroy it. These different leukocytes are now briefly examined.

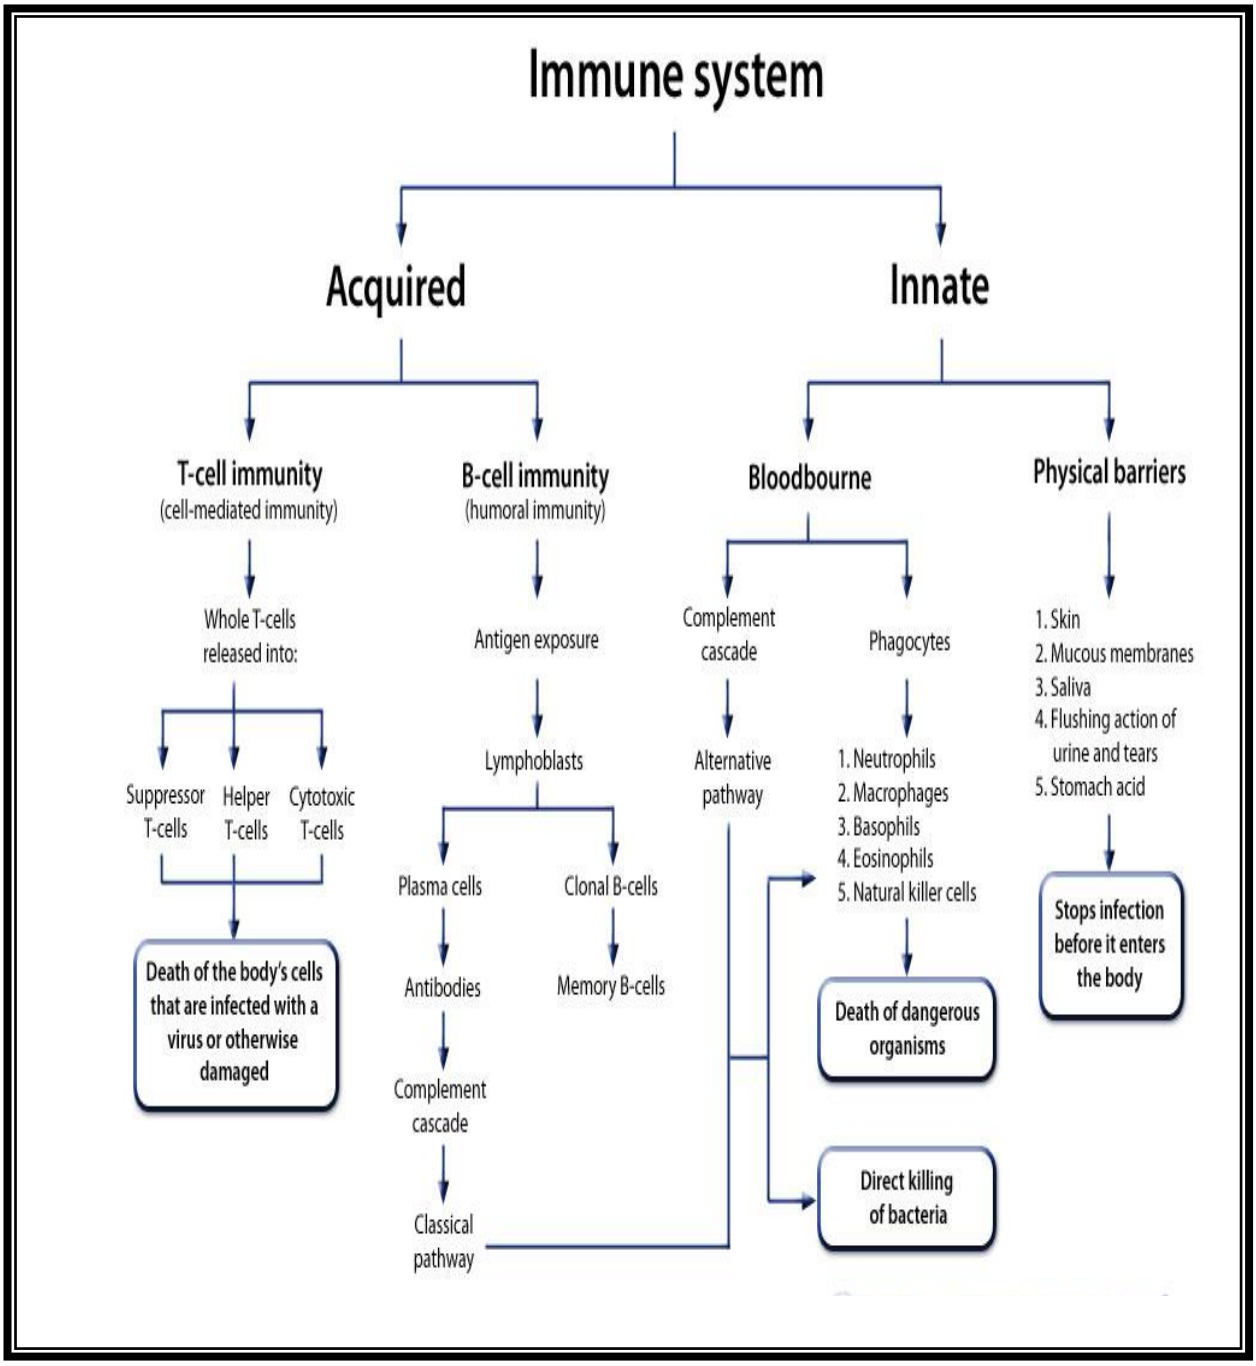
Granulocytes: Granulocytes have irregularly shaped nuclei with two to five lobes. Their cytoplasm has granules that contain reactive substances that kill microorganisms and enhance inflammation.

Three types of granulocytes exist: basophils, eosinophils, and neutrophils. Because of the



irregularly shaped nuclei, neutrophils are also called polymorphonuclear neutrophils, or PMNs.





1. The nonspecific immune response is also known as **nonspecific** resistance and **innate or natural immunity**; it resists any microorganism or foreign material encountered by the vertebrate host. It includes general mechanisms inherited as part of the innate structure and function of each animal (such as skin, mucus, and constitutively produced antimicrobial mediators like lysozyme), and acts as a first line of defense. The nonspecific immune response defends against foreign particles equally and lacks immunological memory that is, nonspecific responses occur to the same extent each time a microorganism or foreign body is encountered.

First line of Defense in natural immunity

A- Physical barriers in nonspecific (innate) resistance

1- **Skin:** The intact skin contributes greatly to nonspecific host resistance. It forms a very effective mechanical barrier to microbial invasion. Its outer layer consists of thick, closely packed cells called keratinocytes, which produce keratins. Keratins are scleroproteins (i.e., insoluble proteins) that make up the main components of hair, nails, and the outer skin cells. These outer skin cells shed continuously, removing any grime or microorganisms that manage to adhere to their surface. The skin is slightly acidic (around pH 5 to 6) due to skin oil, secretions from sweat glands, and organic acids produced by commensal staphylococci. It also contains a high concentration of sodium chloride and is subject to periodic drying.

2- **Mucous Membranes:** The mucous membranes of the eye (conjunctiva) and the respiratory, digestive, and urogenital systems withstand microbial invasion because the intact stratified squamous epithelium and mucous secretions form a protective covering that resists penetration and traps many microorganisms. This mechanism contributes to nonspecific immunity.

3- Respiratory System

The mammalian respiratory system has formidable defense mechanisms. The average person inhales at least eight microorganisms a minute, or 10,000 each day. Once inhaled, a microorganism must first survive and penetrate the air-filtration system of the upper and lower respiratory tracts.

4- Gastrointestinal Tract

Most microorganisms that reach the stomach are killed by gastric juice (a mixture of hydrochloric acid, proteolytic enzymes, and mucus). The very acidic gastric juice (pH 2 to 3) is sufficient to destroy most organisms and their toxins, although exceptions exist (protozoan cysts, Helicobacter pylori, Clostridium and Staphylococcus toxins).

5- The Eye

The conjunctiva is a specialized, mucus-secreting epithelial membrane that lines the interior surface of each eyelid and the exposed surface of the eyeball. It is kept moist by the continuous flushing action of tears (lacrimal fluid) from the lacrimal glands. Tears contain large amounts of lysozyme, lactoferrin, and sIgA and thus provide chemical as well as physical protection.

B- Chemical mediators in nonspecific (innate) resistance

1-Antimicrobial Peptides: A number of proteins that are expressed at epithelial surfaces, and by polymorphonuclear leukocytes (PMNs), can have a direct antibacterial effect. These include beta defensins, dermicidins and cathelicidins. Defensins form 30–50% of neutrophil granules and disrupt the lipid membranes of bacteria. These proteins can have broad activity to directly kill bacteria, yeasts, fungi, viruses and even cancer cells.

2 – Bacteriocins: Bacteriocins are a kind of ribosomal synthesized antimicrobial peptides produced by bacteria, which can kill or inhibit bacterial strains

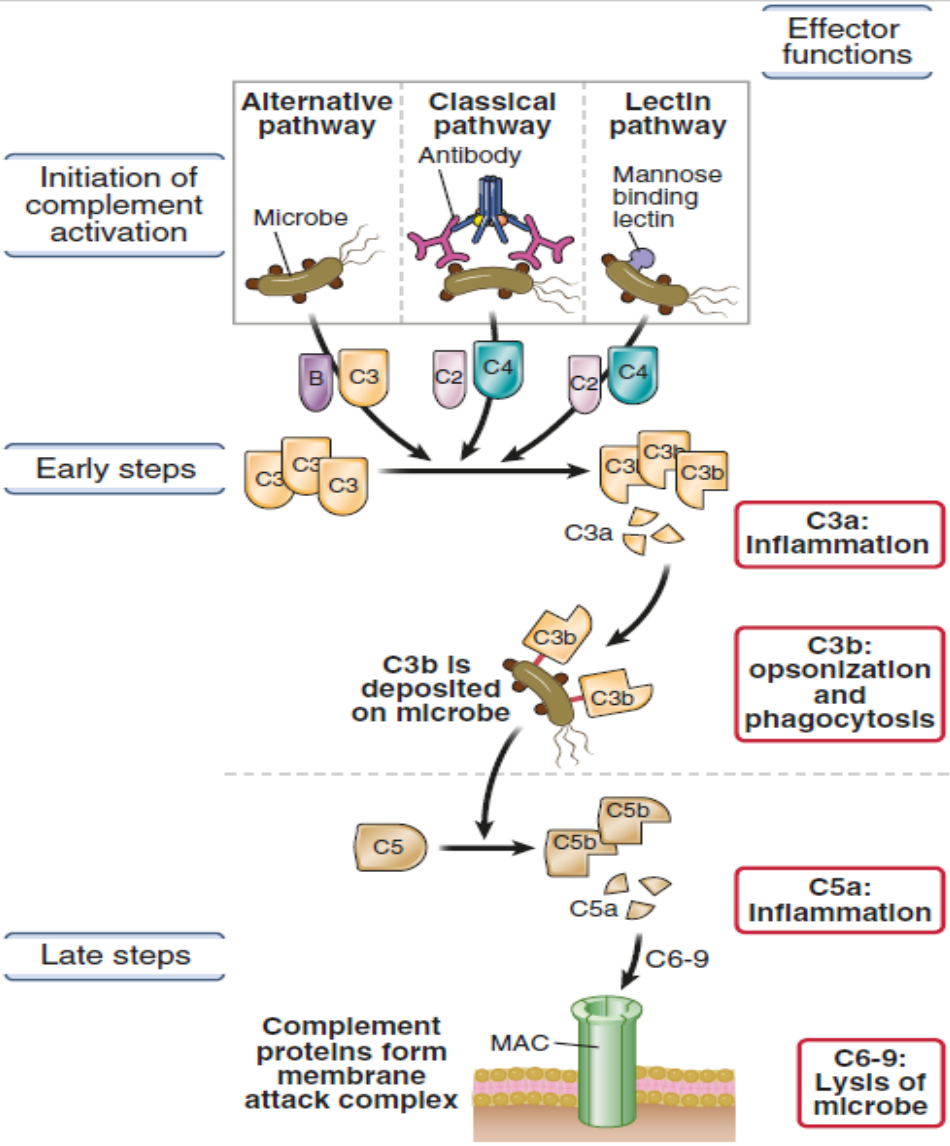
Second line of Defense in natural immunity

A- Complement system

The complement system consists of several plasma proteins (20 or more plasma proteins that interact with one another and with cell membranes). Components of complement have several important roles in defense, including inflammation, phagocytosis, lysis of susceptible microbes, removal of immune complexes, and activation of B cells. The complement system can be activated directly by microbes (alternative and lectin pathways) and through antibodies (IgM and IgG) bound to the microbes (classical pathway). The first step in activation of the complement system is recognition of molecules on microbial surfaces but not host cells, and this occurs in three ways, each referred to as a distinct pathway of complement activation. Many complement proteins are proteolytic enzymes, and complement activation involves the sequential activation of these enzymes. The complement cascade may be activated by any of three pathways.

• The classical pathway is most often triggered by antibodies that bind to microbes or other antigens and is thus a component of the humoral arm of adaptive immunity.

• The lectin pathway (**Lectins are carbohydrate-binding proteins that are highly specific for sugar groups of other molecules**) is activated when a carbohydrate-binding plasma protein, mannose-binding lectin (MBL), binds to terminal mannose residues on the surface glycoproteins of microbes. This lectin activates proteins of the classical pathway, but because it is initiated by a microbial product in the absence of antibody, it is a component of innate immunity.



B- Cytokines

Cytokines include chemokines, interferons, interleukins, lymphokines, and tumour necrosis factors, but generally not hormones or growth factors (despite some overlap in the terminology). Cytokines are produced by a broad range of cells, including immune cells like macrophages, B lymphocytes, T lymphocytes and mast cells, as well as endothelial cells, fibroblasts, and various stromal cells; a given cytokine may be produced by more than one type of cell.

Cytokines are cell-to-cell messengers that contribute to immune responses and incite movement to sites of trauma, inflammation, and infection. Defense against viruses, microorganisms and their products, parasites, and cancer cells are mediated by both nonspecific immunity and specific immunity. The term cytokine is a generic term for any

soluble protein or glycoprotein released by one cell population that acts as an intercellular (between cells) mediator or signaling molecule.

Cytokines include Interleukins, Lymphokines, Monokines, Interferons (IFN), colony stimulating factors (CSF), Chemokines and a variety of other proteins. Type-1 cytokines are cytokines produced by Th1 T-helper cells while Type-2 cytokines are those produced by Th2 T-helper cells. Type-1 cytokines include IL-2 (IL2), IFN-gamma (IFN-G), IL-12 (IL12) & TNF-beta (TNF-b), while Type 2 cytokines include IL-4 (IL4), IL-5 (IL5), IL-6 (IL6), IL-10(IL10), and IL-13 (IL13). When released from mononuclear phagocytes, these proteins are called **Monokines**; when released from T lymphocytes they are called **Lymphokines**; when produced by a leukocyte and the action is on another leukocyte, they are **Interleukins**; and if their effect is to stimulate the growth and differentiation of immature leukocytes in the bone marrow, they are called colony-stimulating factors (CSFs).

C- Phagocytosis

D- Inflammation.

2. The specific immune responses, also known as acquired, adaptive, or specific immunity, resist a particular foreign agent, which occurs after exposure to an antigen (eg, an infectious agent) is specific and is mediated by either antibody or lymphoid cells. It can be passive or active.

Third line of Defense

- **Passive Immunity**

Passive immunity occurs naturally during pregnancy; the mother's IgG antibodies cross the placenta and protect the fetus. These antibodies remain active in the newborn infant during the first few months of life, when the neonate's own immune responses are still developing. Consequently, a number of infectious diseases normally do not occur until a baby is three to six months of age, by which time the maternal antibodies have been degraded. Passive immunity also occurs as a result of breast feeding; the IgA in breast milk protects the alimentary tract of the child. Passive immunity provides no memory; once the transferred antibodies are degraded, the protection is lost. Artificial passive immunity involves transferring antibodies

produced by other people or animals. This type of immunity can be used to prevent disease before or after likely exposure to an infectious agent, to limit the duration of certain diseases, and to block the action of microbial toxins. An antibody preparation that protects against a given toxin is called an antitoxin.

Active Immunity

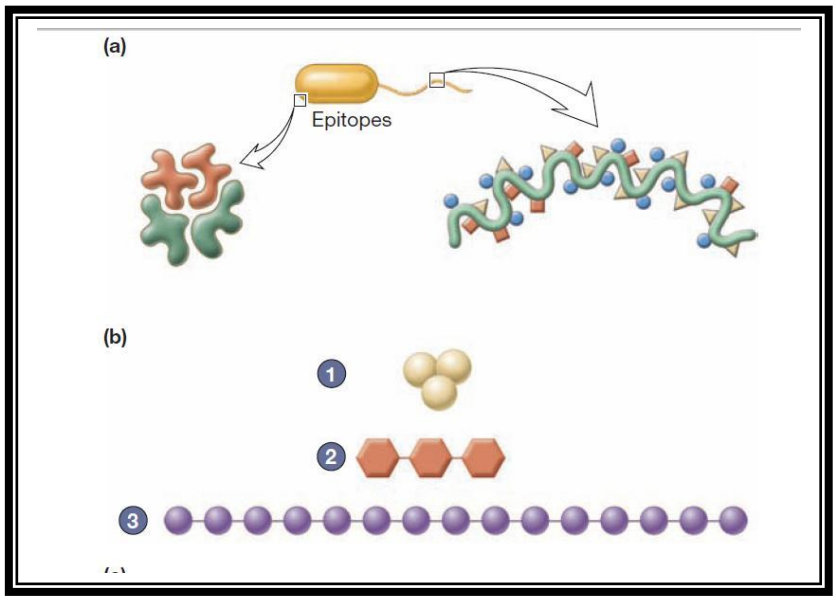
Active immunity is the result of an immune response in an individual upon exposure to antigen. Specific B and T lymphocytes are activated and then proliferate, providing the individual with the lasting protection associated with immunological memory. Active immunity can develop either naturally from an actual infection or artificially from administration of a vaccine.

	Active	Passive
Natural	Natural exposure to antigen induces an immune response; immunity following an attack of measles.	Transfer of antibodies or cells produced by others; temporary immunity from antibodies of the mother transferred to infant across the placenta or in milk.
Artificial	Deliberate exposure to antigen induces an immune response; immunization of children.	Antibodies in immune serum are introduced into body; injection of rabies immune globulin after a dog bite.

ANTIGENS

The immune system distinguishes between “self” and “nonself” through an elaborate recognition process. Self and nonself substances that elicit an immune response and react with the products of that response are often called antigens. Antigens include molecules such as proteins, nucleoproteins, polysaccharides, and some glycolipids. While the term “immunogen” (immunity generator) is a more precise descriptor for a substance that elicits a specific immune response, “antigen” is used more frequently. Most antigens are large, complex molecules with a molecular weight generally greater than 10,000 Daltons (Da).

The ability of a molecule to function as an antigen depends on its size, structural complexity, chemical nature, and degree of foreignness to the host. Each antigen can have several antigenic determinant sites, or epitopes.



a- Complex molecules with several epitopes make good immunogens.

b- Poor immunogens include small molecules not attached to a carrier molecule (*1*), simple molecules (*2*), and (*3*) large but repetitive molecules.

Epitopes are the regions or sites in the antigen that bind to a specific antibody or T-cell receptor through an antigen-binding site.

Haptens

Many small organic molecules are not antigenic by themselves but become antigenic if they bond to a larger carrier molecule such as a protein. These small antigens are called haptens . When lymphocytes are stimulated by the combined hapten-carrier molecule, they can react to either the hapten or the larger carrier molecule. This occurs because the hapten functions as one epitope of the carrier. When the carrier is processed and presented to T cells, responses to both the hapten and the carrier protein can be elicited. As a result, both hapten specific and carrier-specific antibodies can be made. One example of a hapten is penicillin. By itself penicillin is a small molecule and is not antigenic. However, when it is combined with certain serum proteins of sensitive individuals, the resulting molecule becomes immunogenic, activates lymphocytes, and initiates a severe and sometimes fatal allergic immune reaction. In these instances, the hapten is acting as an antigenic determinant on the carrier molecule.

ANTIBODIES

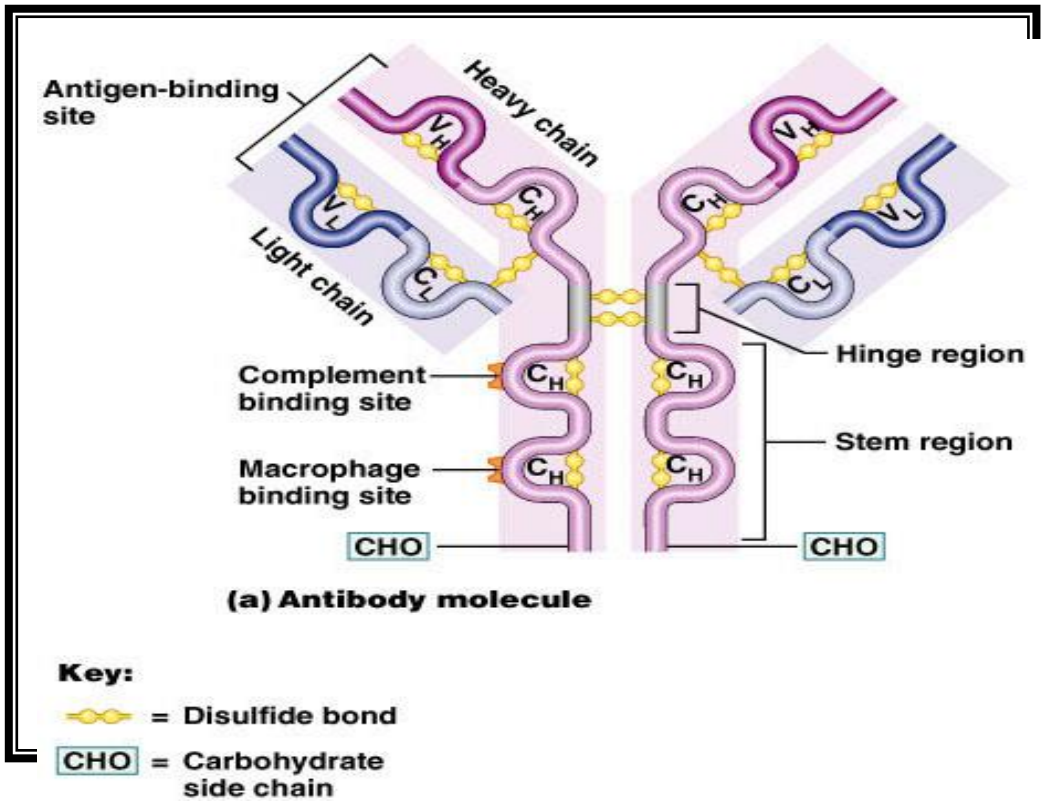
Antibodies are glycoprotein molecules also called immunoglobulins. Each antibody has at least two sites that bind to antigenic determinants. These sites are known as

antigen binding sites.The number of antigen binding sites on an antibody determines the valance of that antibody. Most human antibodies have two binding sites, therefore, they are bivalent.

BASIC ANTIBODY STRUCTURE

1- Consists of four looping polypeptide chains linked together with disulfide bonds. Two identical heavy (H) chains and two identical light (L) chains.

2. The four chains bound together using disulfide bonds to form an antibody monomer which is "Y" shaped.



3. Each chain has a variable (V) region at one end and a constant (C) region at the other end.

4. Both the H and L chains have sections located at the ends of the Y's arms, called (V) regions.

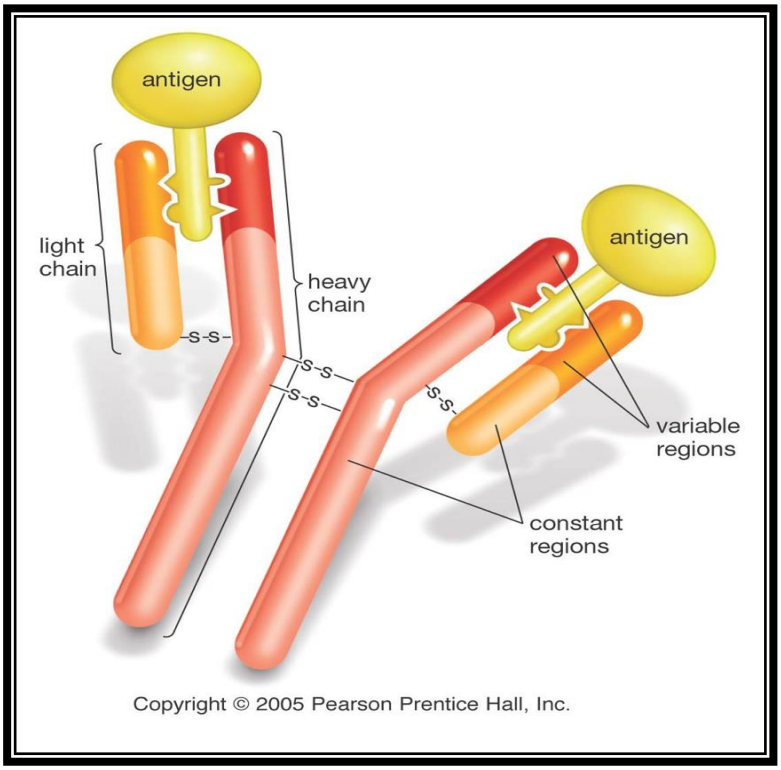
5. Variable regions of the heavy and light chains combine to form the antigen-binding site.

6. The stem of the antibody monomer and lower parts of the Y's arms are called constant (C) regions.

7.There are 5 major sequences found for C regions of H chains, and there are 2 different sequences for L chains.

8.Each H chain sequence determines a different class of immunoglobulin.

9.The stem of the Y shaped antibody monomer is called the Fc



These names were assigned following early studies that showed that enzymatic digestion of antibodies yielded two types of fragments— fragments that were antigen-binding (Fab) and fragments that could be crystallized (Fc).

There are five major classes of human immunoglobulin (Ig) molecules IgM, IgG, IgA, IgD, and IgE. Each class shares the same basic monomeric structure but is distinguished by a characteristic amino acid sequence in the constant portion of the heavy chain. Since this is the part of the molecule that interacts with other "players" of the immune system, the various classes differ in their functional properties. The specialized attributes of each class will be described later, after we consider some of the general characteristics of antibodies.

IgG

1. This monomer is the most abundant and diverse accounts for about 80-85% of all antibodies.
2. These monomers can cross the placenta and confers passive immunity, as well as, blood vessels.
3. Monomers activate complement and increase phagocytosis.
4. These monomers convey long term immunity
5. IgG protect against circulating bacteria and viruses, and bacterial toxins.

IgM

1. This monomer comprises about 5-10% of the antibodies in serum.
2. IgM are the first ones to appear in response to the initial exposure to an antigen.
3. IgM have a pentamer structure.

4. They large size prevent IgM from moving about as freely as IgG, therefore, they remain in the blood vessels.
5. They fix complement.

IgA

1. This monomer accounts for about 15% of the antibodies in serum.
2. IgA can be monomers or dimers.
3. IgA monomers are found in salvia, sweat, breast milk, and secretions of the G.I. tract.
4. They do not fix complement
5. The main function of IgA is to prevent the attachment of pathogens to mucosal surfaces.

IgD

1. IgD atibodies comprise only about 0.2% of the total serum antibodies.
2. IgD antibodies are found in blood and lymph and on the surfaces of B cells.
3. They do not fix complement.
4. They help to initiate the immune response.

IgE

1. IgE antibodies comprise about 0.002% of the total number of antibodies.
2. IgE molecules bind tightly by their Fc ends to receptors on mast cells and basophils. This causes the release of histamine.
3. They do not fix complement.

TABLE 15.2

Characteristics of the Immunoglobulin (Ig) Classes

	Monomer	Dimer, Monomer	Pentamer	Monomer	Monomer
Number of Antigen Binding Sites	2	4 2	10	2	2
Molecular Weight	150,000	170,000–385,000	900,000	180,000	200,000
Percent of Total Antibody in Serum	80%	13%	6%	1%	0.002%
Average Life in Serum (Days)	23	6	5	3	2.5
Crosses Placenta?	Yes	No	No	No	No
Fixes Complement?	Yes	No	Yes	No	No
Fc Binds To	Phagocytes	Phagocytes	B lymphocytes	B lymphocytes	Mast cells and basophils
Biological Function	Long-term immunity; memory antibodies	Secretory antibody; on mucous membranes	Produced at first response to antigen; can serve as B-cell receptor	Receptor on B cells	Antibody of allergy; worm infections

C = carbohydrate.
J = J chain.

The Complement System

The complement system consists of approximately 20 proteins that are present in normal human (and other animal) serum. The term "complement" refers to the ability of these proteins to complement, i.e., augment, the effects of other components of the immune system, e.g., antibody. Complement is an important component of our innate host defenses Several complement components are proenzymes, which must be cleaved to form active enzymes. Activation of the complement system can be initiated either by antigen–antibody complexes or by a variety of nonimmunologic molecules, e.g.,endotoxin Sequential activation of complement components occurs via one of three pathways: the classic pathway, the lectin pathway, and the alternative pathway.

Of these pathways, the lectin and the alternative pathways are more important the first time we are infected by a microorganism because the antibody required to trigger the classic pathway is not present.

There are three main effects of complement:

(1) Lysis of cells such as bacteria, allografts, and tumor cells.
(2) Generation of mediators that participate in inflammation and attract neutrophils.

(3) Opsonization, i.e., enhancement of phagocytosis.

Complement proteins are synthesized mainly by the liver.

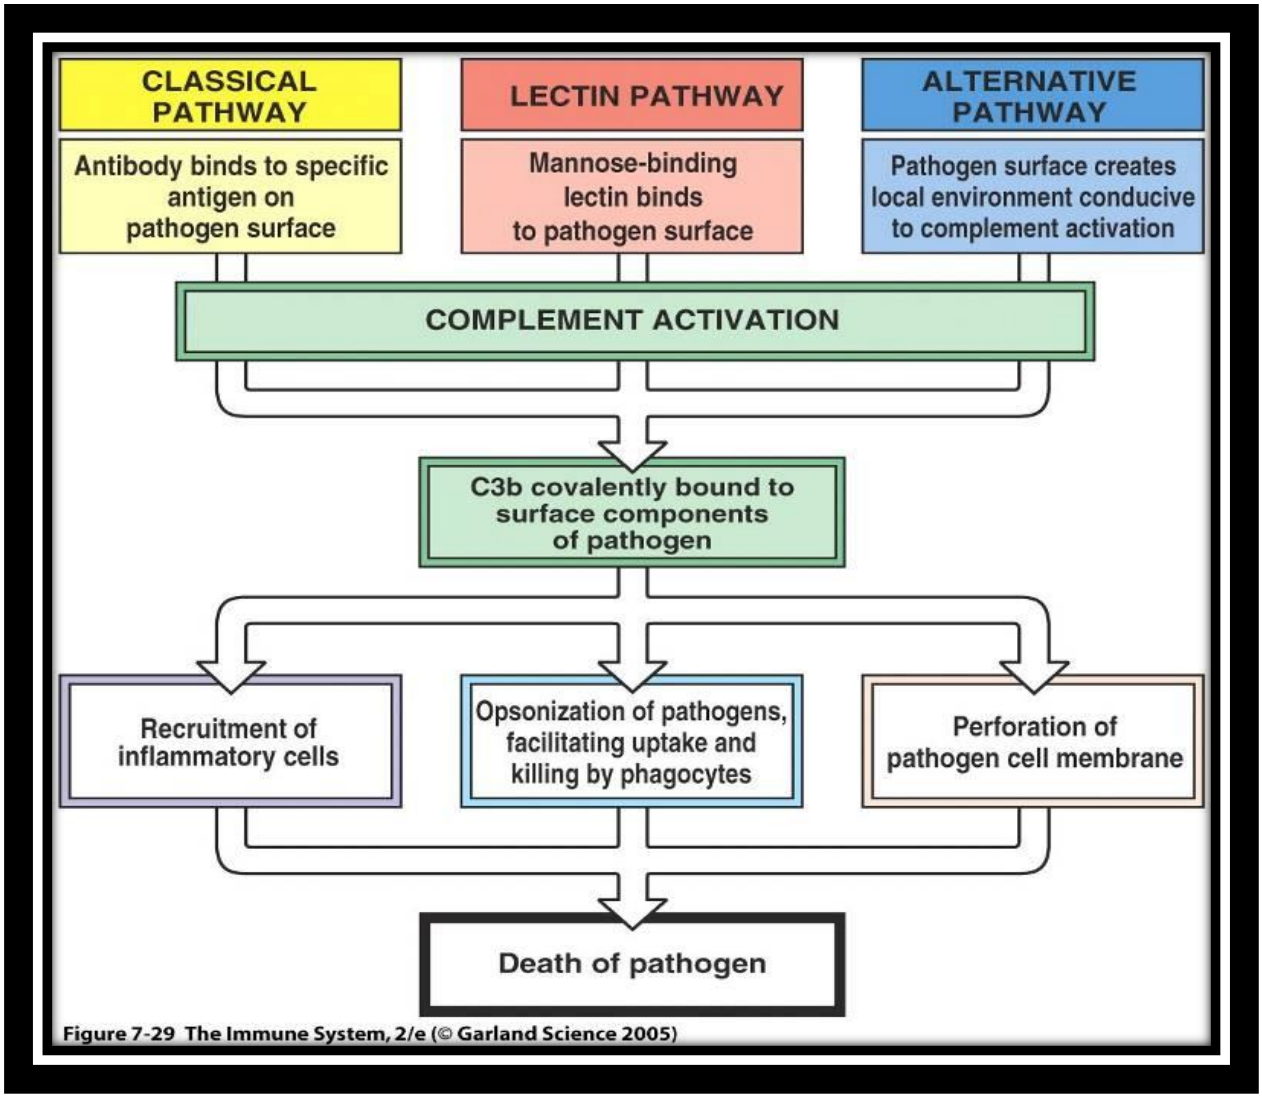
- Remember 3 Key Words
  - **ACTIVATION**
  - **AMPLIFICATION**
  - **ATTACK**

Pathways of complement activation

1- **Classic pathway**
   - Activated by antibody

2- **Alternative pathway**
   - Activated by some bacterial cell surfaces
   - Antibody not involved

3- **Lectin pathway**
   - Activated by mannose binding lectin
   - Antibody not involved



1- **Classic pathway of complement activation**

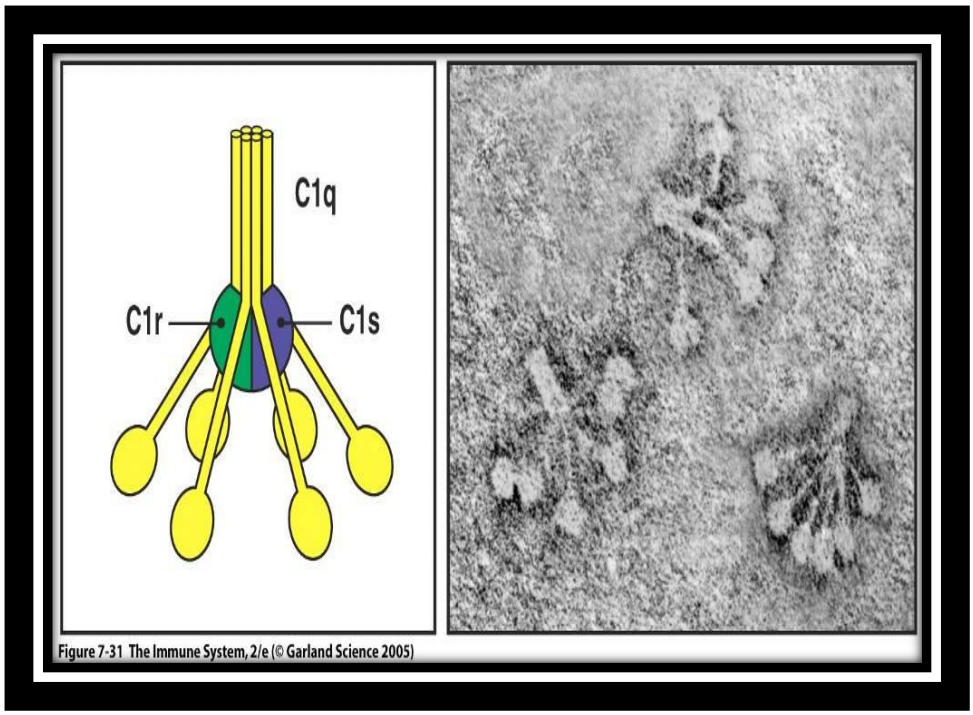
A. The proteins in this pathway are named C1-C9 .

B. C1 is complex of 3 proteins

a. C1q is binding protein

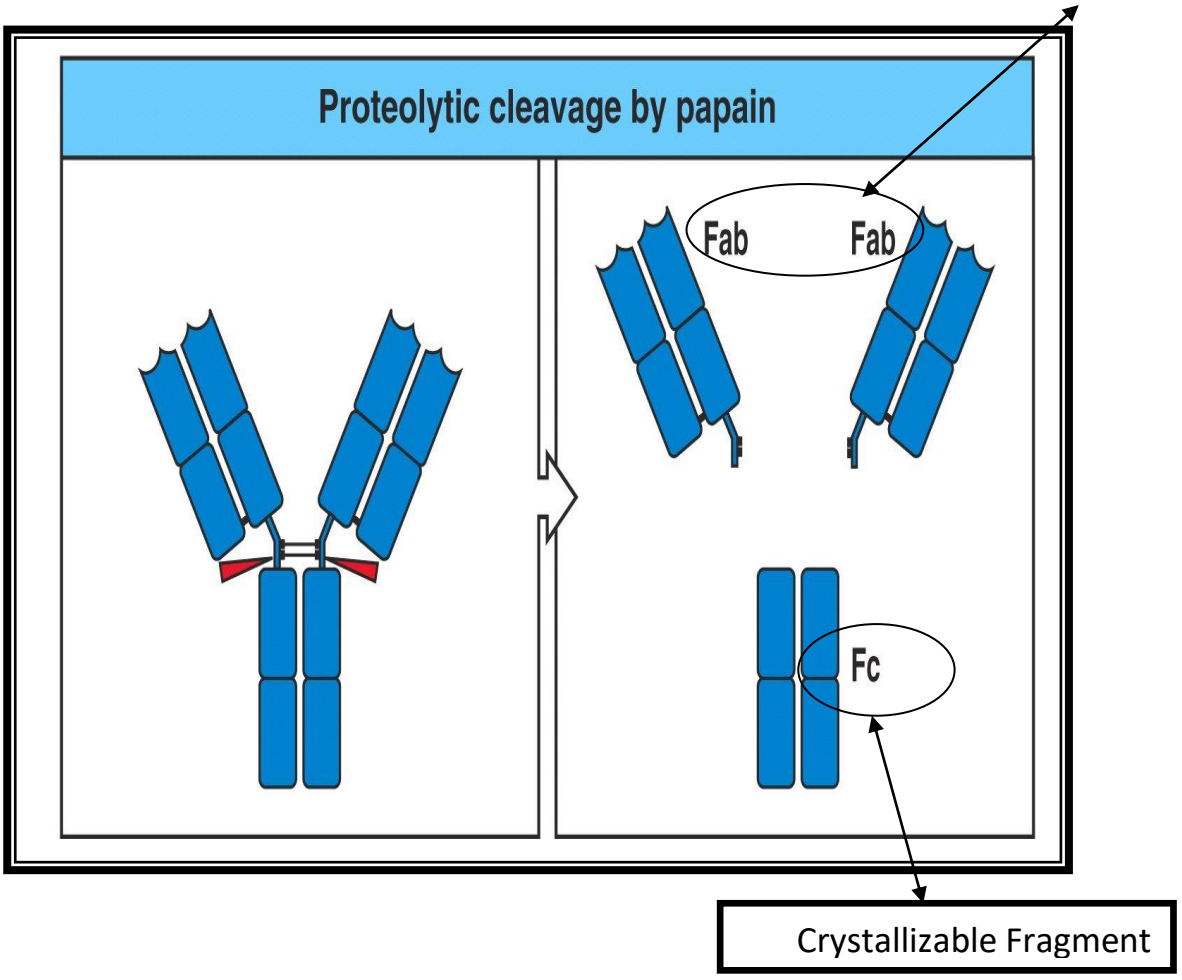
b. C1r and C1s are proteases

c. C1s binds to Fc region of antibody part of Ab/Ag complex



Component in serum	Active form
C1	C1q
	C1r
	C1s
C4	C4b
	C4a
C2	C2b
	C2a
C3	C3b
	C3a

C1q binds to Fc region of antibody which activates C1r which activates C1s, Most efficient at activation complement IgM, IgG1 and IgG3.



- Begins with antibody binding to a cell surface and ends with the lysis of the cell
- The proteins in this pathway are named C1-C9.
- When complement is activated it is split into two parts
  - a – smaller of the two parts
  - B – larger part and usually the active part (except with factor 2)
- **ACTIVATION**
  - **C1q** portion of C1 attaches to the Fc portion of an **antibody**

- Only **IgG** and **IgM** can activate complement
- Once activated C1s is eventually cleaved which activates C4 and C2
- C4b & C2a come together to form the **C4b2a** which is the **C3 convertase**
- C3 convertase activates C3 to C3a and C3b
- **C3a** binds to receptors on **basophils** and **mast cells** triggering them to release there vasoactive compounds (enhances vasodilation and vaso-permeability)
- **C3a** is called an **anaphylatoxin**
- **C3b** serves as an opsonin which facilitates immune complex clearance .

■ **AMPLIFICATION**

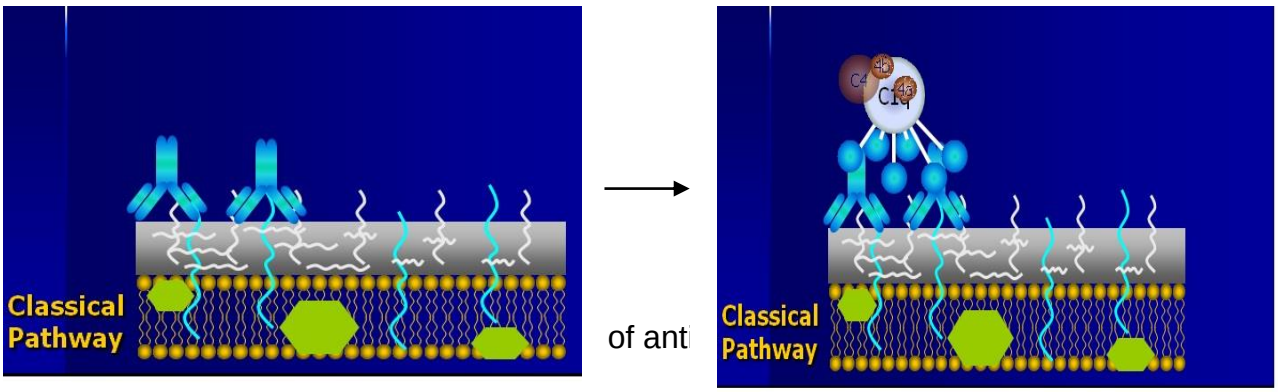
-Each C1s creates many C4b and C2b fragments

-Each C4bC2a creates many C3b (activated C3)

-Each C3b goes on to create many Membrane Attack Complexes.

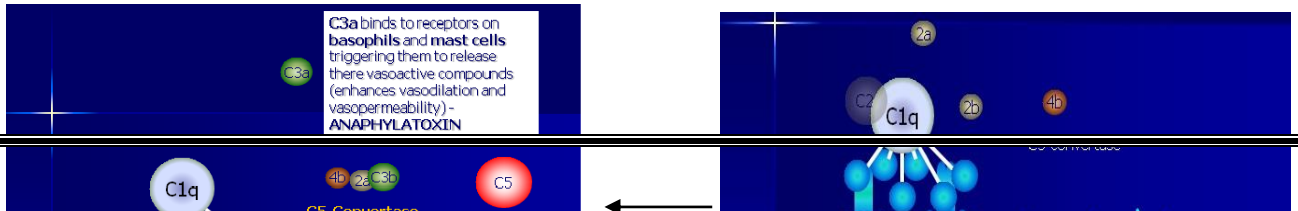
■ **ATTACK**

- Most C3b serves an opsonin function
- Some C3b binds to C4bC2a to form the **C5 convertase C4bC2aC3b**
- C5 convertase cleaves C5 leading to the formation of the Membrane attack Complex (C5-C6-C7-C8-C9)
- The MAC “punches holes” in cell walls resulting in lysis



of ant

■ C3



- Factor D* and
- Properdin

❖ **First step:** binding of C3b to foreign cell or surface

❖ **ACTIVATION**

- Spontaneous conversion from C3 to C3b occurs in body
- Normally, C3b is very short lived and quickly inactivated by proteins on the surface of the body's own cell walls
- However, bacteria or other foreign material may lack these surface proteins allowing C3b to bind and stay active

❖ **AMPLIFICATION**

- Factor B binds to C3b
- Factor B is then cleaved by factor D into Ba and Bb
- C3bBb remains which acts as a C3 convertase (C3 ➔ C3a and C3b)
- C3bBbC3b is formed which acts as a C5 convertase

❖ **ATTACK**

- C5 is cleaved to C5a and C5b
- C5b then starts the assembly of the Membrane Attack Complex

General structure and classification of viruses

General properties of viruses:

1. Viruses are smaller than bacteria, they range in size between 20-300 nanometer (nm) (Table 2-1).

2. Viruses contain only one type of nucleic acid, either DNA or RNA, but never both.

3. Viruses consist of nucleic acid surrounded by a protein coat. Some viruses have additional lipoprotein envelope.

4. Viruses lack cellular organelles, such as mitochondria and ribosomes.

5. Viruses are obligate cellular parasites. They replicate only inside living cells.

6. Viruses replicate through replication of their nucleic acid and synthesis of the viral protein.

7. Viruses do not multiply in chemically defined media.

8. Viruses do not undergo binary fission.

Virus is a broad general term for any aspect of the infectious agent and includes:
• the infectious or inactivated virus particle

• viral nucleic acid and protein in the infected cell

Virion is the physical particle in the extra-cellular phase which is able to spread to new host cells; complete intact virus particle is able to spread to new host cells; complete intact virus particle.

Table (2-1) : Comparison between viruses and bacteria

Comparison between viruses and bacteria

No.	Property	Viruses	Bacteria
1	Size	20-300 nm	1000 nm
2	Genome (type of nucleic acid)	DNA or RNA but not both	DNA and RNA
3	Cell wall	Envelope present in some viruses	Cell wall
4	Ribosomes	No ribosomes	Ribosomes
5	Multiplication by binary fission	_	+
6	Sensitivity to antibiotics	_	+
7	Growth in culture media	Grow only in living host cell	Grow in culture media

The structure of viruses:

1. Viral nucleic acid:

The viral nucleic acid is located internally and can be either single- or double-stranded RNA or DNA. The nucleic acid can be either linear or circular. The DNA is always a single molecule; the RNA either can exist as a single molecule or in several pieces (segmented).

• Some RNA viruses are positive polarity and others are negative polarity.

• Positive polarity is defined as an RNA with same base sequence as the mRNA. (Positive strand RNA)

• Negative polarity has a base sequence that is complementary to the mRNA. (Negative strand RNA) (Figure 2-1)

2. Capsid:

The protein shell, or coat, that encloses the nucleic acid genome and mediates the attachment of the virus to specific receptors on the host cell surface.

3. **Capsomeres:**

Morphologic units seen in electron microscope. Each capsomere, consisting of one or several proteins.

Naked viruses are composed of nucleic acid + capsid (nucleocapsid)

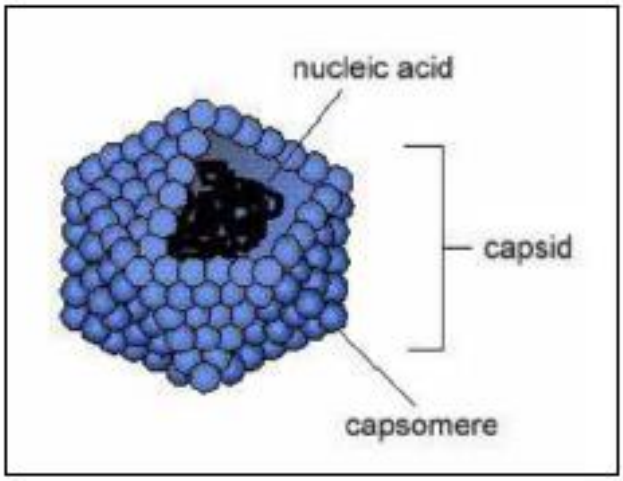

Figure 2-1 Naked virus composition

4. Viral envelope:

The envelope is a lipoprotein membrane composed of lipid derived from the host cell membrane and protein that is virus- specific. Furthermore, there are frequently glycoproteins in form of spike-like projections on the surface, which attach to host cell receptors. Matrix protein mediates the interaction between the capsid proteins and envelope. The presence of an envelope confers instability on the virus Enveloped viruses NA + capsid + envelope

The whole virus particle is called virion. (Figure 2-2)

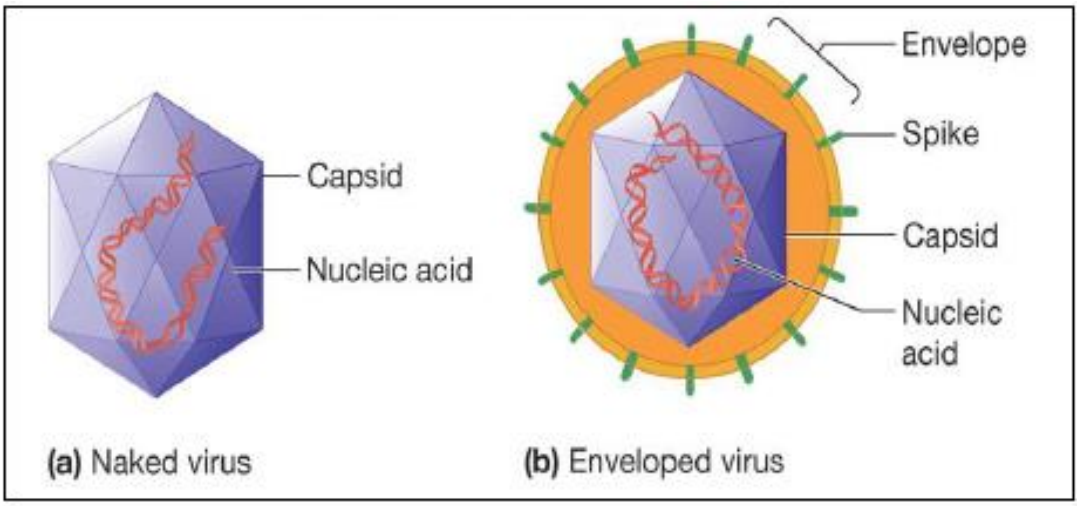

Figure 2-2 illustrate the difference between enveloped virus and naked virus

Reaction to physical and chemical agents:

1. Heat and cold: Viral infectivity is generally destroyed by heating at 50-60 C^0 for 30 mint. Viruses can be preserved at -90 C0 or -196 C^0 (liquid nitrogens).

2. PH: Viruses can be preserved at physiological PH (7.3).

3. Ether susceptibility: Ether susceptibility can be used to distinguish viruses that possess an envelope from those that do not.

4. Detergents: Nonionic detergents solubilize lipid constituents of viral membranes. The viral proteins in the envelope are released Anionic detergents also solubilize viral envelopes; in addition, they disrupt capsids into separated polypeptides.

Viral Replication:

Steps in Viral Replication:

A. Attachment:

This is the first step in viral replication. Surface proteins of the virus interact with specific receptors on the target cell surface.

B. Penetration:

Enveloped with the viruses (e.g., HIV, influenza virus) penetrate cells through fusion of the viral envelope host cell membrane. Non-enveloped viruses penetrate cells by translocation of the virion across the host cell membrane or receptor mediated endocytosis.

C. Un-coating:

This process makes the nucleic acid available for transcription to permit multiplication of the virus.

D. Transcription and Translation:

The fact that viruses must use host cellular machinery to replicate and make functional and structural proteins. Assembly and Release. The process of virion assembly involves bringing together newly formed viral nucleic acid and the structural proteins to form the nucleo-capsid of the virus

E. Virus Shedding:

This is a necessary step to maintain a viral infection in populations of hosts. Shedding usually occurs from the body surfaces involved in viral entry. Shedding occurs at different stages of disease depending on the particular agent involved.

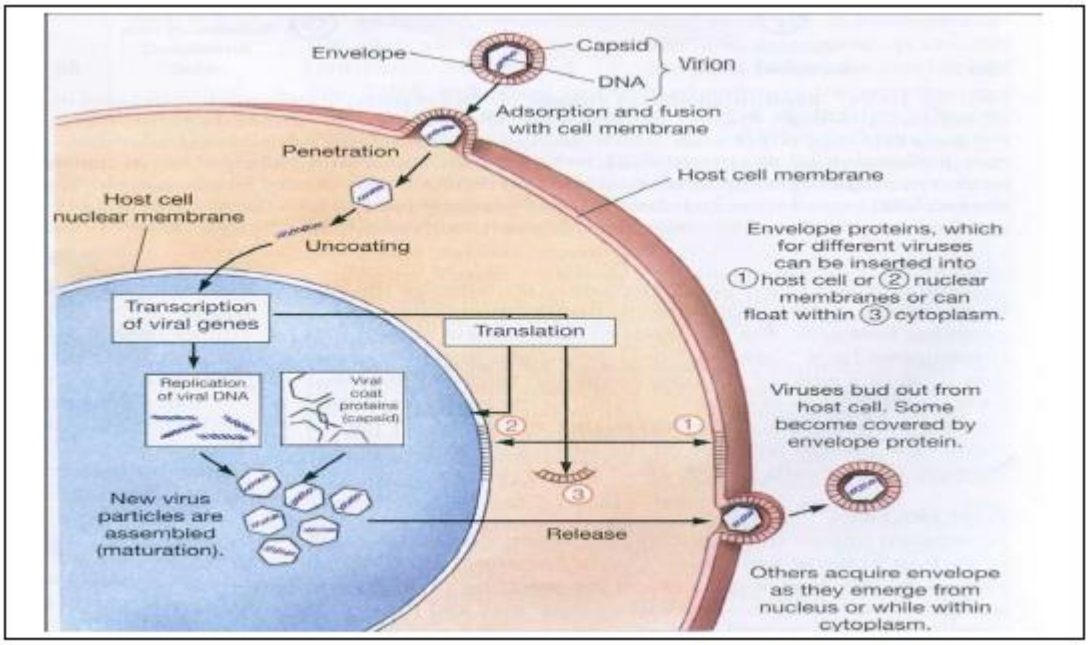

Figure (2-4) steps of viral replication

Routs of infection

- Inhalation; e.g influenza viruses
- Ingestion: polioviruses
- Parenteral: AIDs
- Trans placental, cytomegalovirus, rubella.

Viral Spread and Cell Tropism

Many viruses produce disease at sites distant from their point of entry. Spread within the host . Mechanisms of viral spread vary, but the most common route is via the bloodstream or lymphatics. The presence of virus in the blood is called viremia.

Mechanisms of viral injury

1. Inhibits host cell DNA, RNA or protein synthesis e.g. Poliovirus.
2. Direct cell killing by damaging host cell membrane e.g. Rhinoviruses.
3. Induce Immune reaction e.g hypersensitivity reaction in respiratory syncytial viruses.
4. Damage host defiance mechanism e.g. respiratory epithelium predisposes to the pneumonia
5. Induce cell proliferation & transformation result in neoplasia e.g. HBV, EBV.

A successful anti-viral drug should:

The life cycle of a virus comprises several stages such as binding to the cell surface, replication, protein synthesis etc. and all of these stages may be the target of anti-viral drugs. Antiviral drugs specifically inhibit one or more steps of virus replication without causing unacceptable side effects. Because of the close interaction between virus replication and normal cellular metabolism, it was originally thought too difficult to interrupt the virus replicative cycle without adversely affecting the host cell metabolism.

The mechanism of action vary among antiviral:

1. Nucleoside and nucleotide Analogs:

The majority of available antiviral agents are nucleoside analogs. They inhibit nucleic acid by inhibition of polymerases essential for nucleic acid replication. In addition, some analogs can be incorporated into the nucleic acid and block further synthesis or alter its function. Example for nucleoside analogs include acyclovir , lamivudine ,ribavirin and zidovudine : AZT Acyclovir (Zovirax) represents a major breakthrough in the treatment of herpes virus infections.

2. Reverse transcriptase inhibitor:

It acts by binding directly to reverse transcriptase and disrupting the enzyme's catalytic site, for example Nevirapine.

3. Protease inhibitor:

Saquinavir was the first protease inhibitor to be approved for treatment of HIV infection, which inhibit viral protease that is required for the last stage of replicative cycle. Inhibition of the protease yields noninfectious virus particles.

Vaccine:

A vaccine is a biological preparation that provides active acquired immunity to a particular disease. A vaccine typically contains an agent that resembles a disease-causing microorganism and is often made from weakened or killed forms of the microbe,

Type of viral vaccine:

There are four categories of vaccines in clinical trials: **WHOLE VIRUS**, **PROTEIN SUBUNIT**, **VIRAL VECTOR** and **NUCLEIC ACID** (RNA AND DNA).

1. Attenuated live viral vaccines

These attenuated viruses can infect and replicate in the recipient and produce a protective immune response without causing disease. Live attenuated viral vaccines can often confer lifelong immunity after one immunization series (.

Live-attenuated vaccines

- Measles, mumps, rubella (MMR combined **vaccine**)
- Rotavirus.
- Smallpox.
- Chickenpox.
- Yellow fever

2. Killed (inactivated) viral vaccines

Killed viral vaccines contain either whole virus particles, inactivated by chemical or physical means, or some component(s) of the virus. They do not generally produce lifelong immunity following one immunization series (e.g.: Rabies vaccine, Injectable poliomyelitis vaccine (IPV)

3. Recombinant-produced antigens

Application of a recombinant DNA strategy to develop new vaccines (Subunit vaccines use pieces of the pathogen - often fragments of protein). This approach has made possible a safe and effective recombinant vaccine against hepatitis B virus, which has replaced the vaccine derived from the plasma of hepatitis B virus-infected individuals.

4. Nucleic acid

Nucleic acid vaccines use genetic material – either RNA or DNA – to provide cells with the instructions to make the antigen. In the case of COVID-19, this is usually the viral spike protein. Once this genetic material gets into human cells, it uses our cells' protein factories to make the antigen that will trigger an immune response.

Type of Vaccines

Herpesviruses OR Herpesviridae

Classification

Herpesviruses are divided into three groups: The **α herpesviruses**, herpes simplex virus types 1 and 2, and varicella-zoster virus, have a short replicative cycle and have a broad host range; **β herpesviruses**, cytomegalovirus, and human herpesviruses 6 and 7, with a long replicative cycle and restricted host range; and **γ herpesviruses**, Epstein-Barr virus and human herpesvirus 8, with a very restricted host range.

A. Alphaherpesviruses - HSV-1, HSV-2, VZV

B. Betaherpesviruses - CMV, HHV-6, HHV-7

C. Gammaherpesviruses - EBV, HHV-8

Nine herpesvirus types are known to primarily infect humans, at least five of which – herpes simplex viruses 1 and 2 (HSV-1 and HSV-2, also known as HHV-1 and HHV-2; both of which can cause orolabial herpes and genital herpes), varicella zoster virus (or HHV-3; the cause of chickenpox and shingles), Epstein–Barr virus (EBV or HHV-4; implicated in several diseases, including mononucleosis and some cancers), and human cytomegalovirus (HCMV or HHV-5) – are extremely widespread among humans.

More than 90% of adults have been infected with at least one of these, and a latent form of the virus remains in almost all humans who have been infected. The less-common human herpesviruses are human herpesvirus 6A and 6B (HHV-6A and HHV-6B), human herpesvirus 7 (HHV-7), and Kaposi's sarcoma-associated herpesvirus (KSHV, also known as HHV-8)

General Biology of Human Herpesviruses

Of the more than 100 known herpesviruses, 9 routinely infect only humans:

- **Herpes simplex virus types 1 and 2** (HSV-1 and HSV-2 both of which can cause orolabial herpes and genital herpes.

- **Varicella-zoster virus (cause of chickenpox and shingles OR belt of fire).**

Symptoms of shingles

The main symptom of shingles is pain, followed by a rash that develops into itchy blisters, similar in appearance to chickenpox. New blisters may appear for up to a week, but a few days after appearing they become yellowish in color, flatten and dry out. Shingles is most common in people over the age of 50 years. However, the virus may reappear in people of all ages who have previously had chickenpox.

Causes of shingles

Most people have chickenpox in childhood, but after the illness has gone, the varicella-zoster virus remains dormant (inactive) in the nervous system. The immune system keeps the virus in check, but later in life it can be reactivated and cause shingles. It's possible to have shingles more than once, but it's very rare to get it more than twice. It's not known exactly why the shingles virus is reactivated at a later stage in life, but most cases are thought to be caused by having lowered

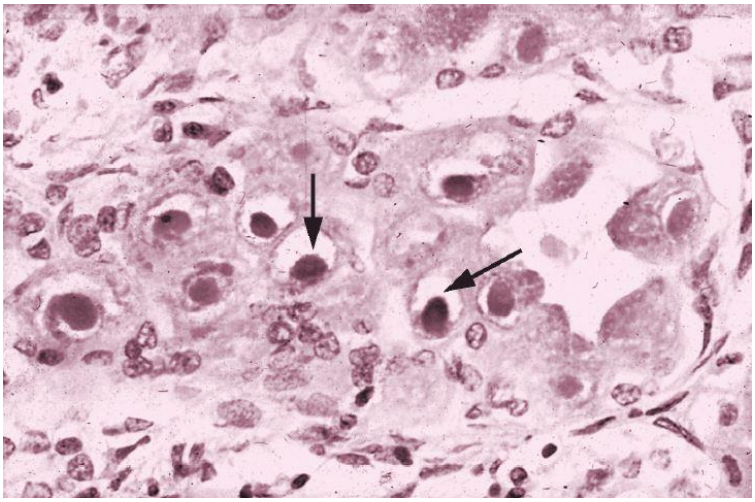
immunity (protection against infections and diseases). Shingles typically resolve within 2 to 4 weeks, and most young, healthy individuals make a full recovery. Approximately 1-4 percent of people who develop shingles require hospitalization for complications.

- **Cytomegalovirus**: causes three clinical syndromes. (1) Congenital cytomegalovirus infection (when symptomatic) causes hepatosplenomegaly, retinitis, rash, and central nervous system involvement.

  Human cytomegalovirus (HCMV) is a ubiquitous virus infection with worldwide distribution. The virus is the most significant infectious cause of congenital disease, an important opportunist in the immunocompromised host and an occasional cause of febrile illness as well as infectious mononucleosis in the general population. CMV is transmissible to the fetus via the placenta, and is an important cause of neonatal morbidity and mortality.

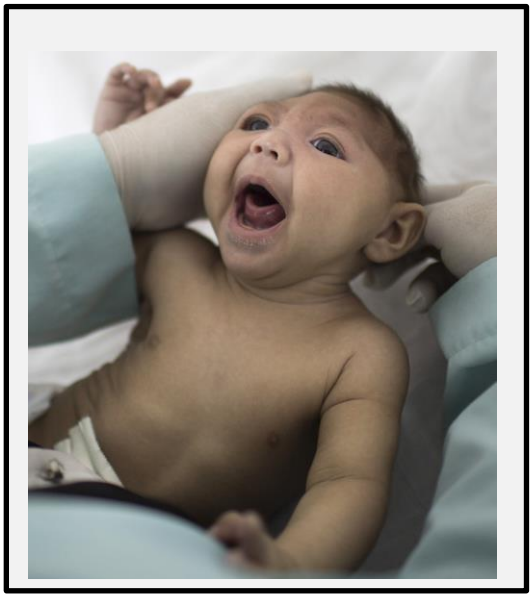
  HCMV infection in humans initiates when exposure to virus infected body fluids overcomes innate immune barriers and sustains replication and dissemination. These events occur most frequently at mucosa sites. A systemic infection takes place where virus can be detected in a peripheral blood mononuclear cell (PBMC

leukocytes T cells, B cells, NK cells) and monocytes) that are responsible for dissemination to salivary glands and kidneys.

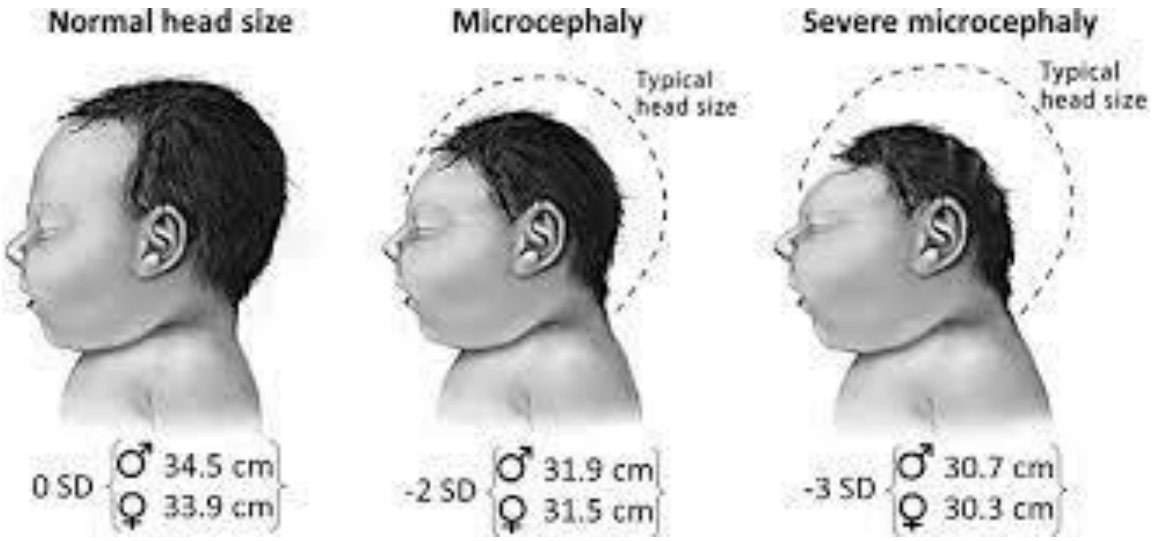


The following signs and symptoms are more common in babies who have congenital CMV and who are sick at birth:

- Premature birth
- Low birth weight
- Yellow skin and eyes (jaundice)
- Enlarged and poorly functioning liver
- Purple skin splotches or a rash or both
- Abnormally small head (microcephaly)
- Enlarged spleen
- Pneumonia



Abnormally small head (microcephaly)

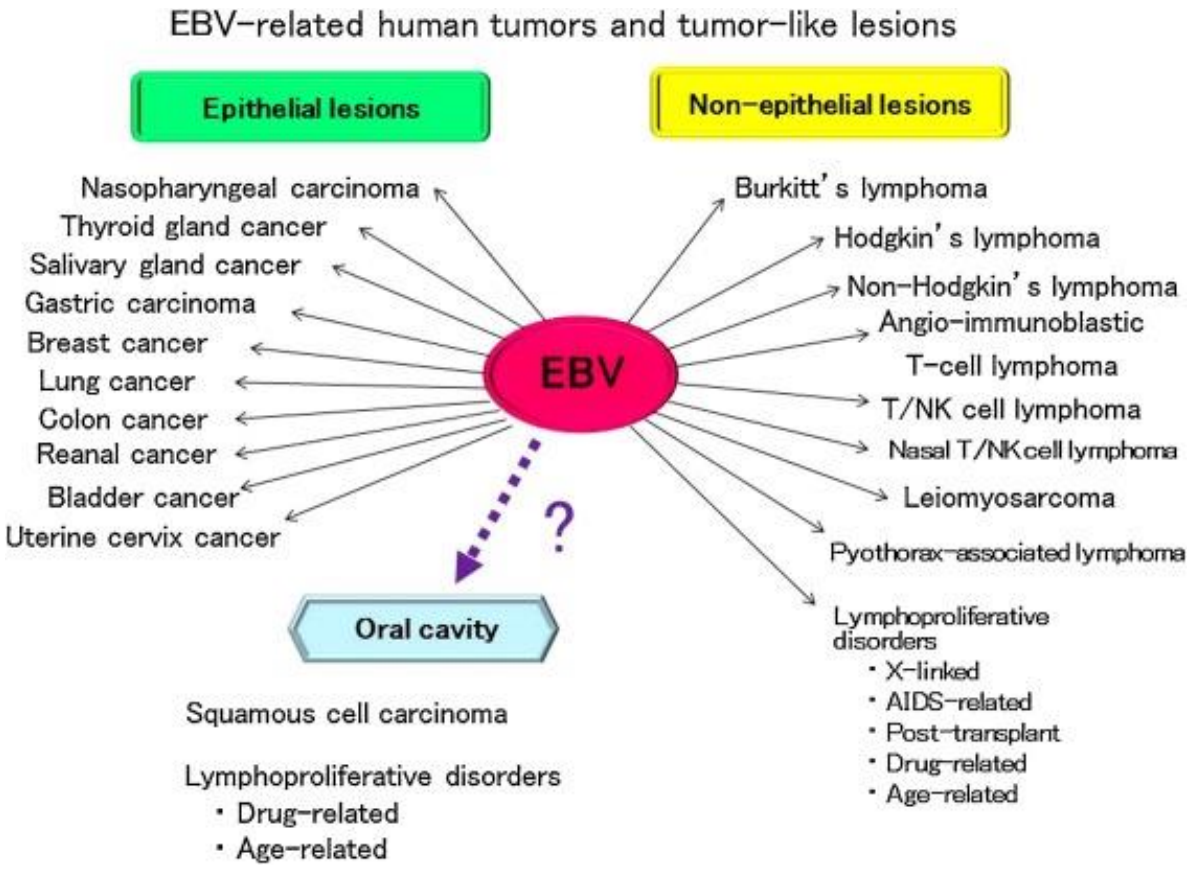


Normal and Abnormally small head (microcephaly)

- **Epstein-Barr virus**: **causes classic mononucleosis**

The Epstein-Barr virus (or EBV) have been consistently found to be associated with some types of B-cell lymphomas. B lymphocytes and epithelial cells are the major sites for EBV infection in the human host. EBV binding to B cells is mediated by CD2 1 , also known as complement receptor 2 (CR2). Over 900/o of adults are infected with EBV Infection is most common between the ages of 2 and 4 years and at around age 1 5 years.

In contrast to B-cell entry, EBV entry into epithelial cells occurs at the cell surface in the absence of endocytosis. In addition to CD2 l , which is expressed on tonsilar epithelial cells, suggesting the gp3 50/220 interaction with CD2 1 may be important for epithelial cell infection,688 BMRF2 may also have a role in epithelial entry.



Other Human Herpes Viruses

- **Human herpesvirus 6 and 7**

Properties of HHV-6 and 7

• Belong to the beta-herpes virus subfamily of herpes viruses

• Double stranded DNA genome of 170 kbp

• The main target cell is the T-lymphocyte, although B-lymphocytes may also be infected.

• HHV-6 and HHV-7 share limited nucleotide homology and antigenic cross-reactivity.

• It is thought that HHV-6 and HHV-7 are related to each other in a similar manner to HSV-1 and HSV-2.

Clinical Manifestations

• Primary HHV-6 infection is associated with **Roseola infantum** , which is a classical disease of childhood. The virus can enter the body through the nose and mouth. It is spread when a child breathes in droplets that contain the virus after an infected person coughs, sneezes, talks, or laughs.

• Most cases occur in infants between the ages of 4 months and two years.

• A spiking fever develops over a period of 2 days followed by a mild rash. The fever is high enough to cause febrile convulsions.

• There are reports that the disease may be complicated by encephalitis.

- **Human Herpes Virus 8**

• Belong to the gammaherpesviruses subfamily of herpesviruses

• Originally isolated from cells of Kaposi’s sarcoma (KS). Kaposi's sarcoma is a type of cancer that forms in the lining of blood and lymph vessels. The tumors (lesions) of Kaposi's sarcoma typically appear as painless purplish spots on the legs, feet or face. Lesions can also appear in the genital area, mouth or lymph nodes.

• HHV-8 DNA is found in almost 100% of cases of Kaposi’s sarcoma

• Most patients with KS have antibodies against HHV-8 .

• Unlike other herpes viruses, HHV-8 does not have a ubiquitous distribution.

Paramyxovirus virus

One of a group of RNA viruses that are predominantly responsible for acute respiratory diseases and are usually transmitted by airborne droplets. The paramyxoviruses include the agents of mumps, measles (Rubeola virus), Rubella, RSV (respiratory syncytial virus), and parainfluenza.

1- Mumps

Mumps is caused by the mumps virus (MuV). Humans are the only natural host of the mumps virus. MuV's genome is made of RNA and contains seven genes that encode nine proteins.

Clinical aspects: The onset is marked by malaise and fever followed within 24 hours by a painful enlargement of one or both parotid glands; the other salivary glands are less often affected. In most cases, the swelling subsides within a few days and recovery is uneventful.

Central nervous system: The incidence of 'aseptic' meningitis is higher after mumps than after any other acute viral infection of childhood. Rates of 0.3–8.0 per cent have been reported in the USA. This complication almost always resolves without sequelae. Postinfection encephalitis is, however, more serious and carriesan appreciable mortality.

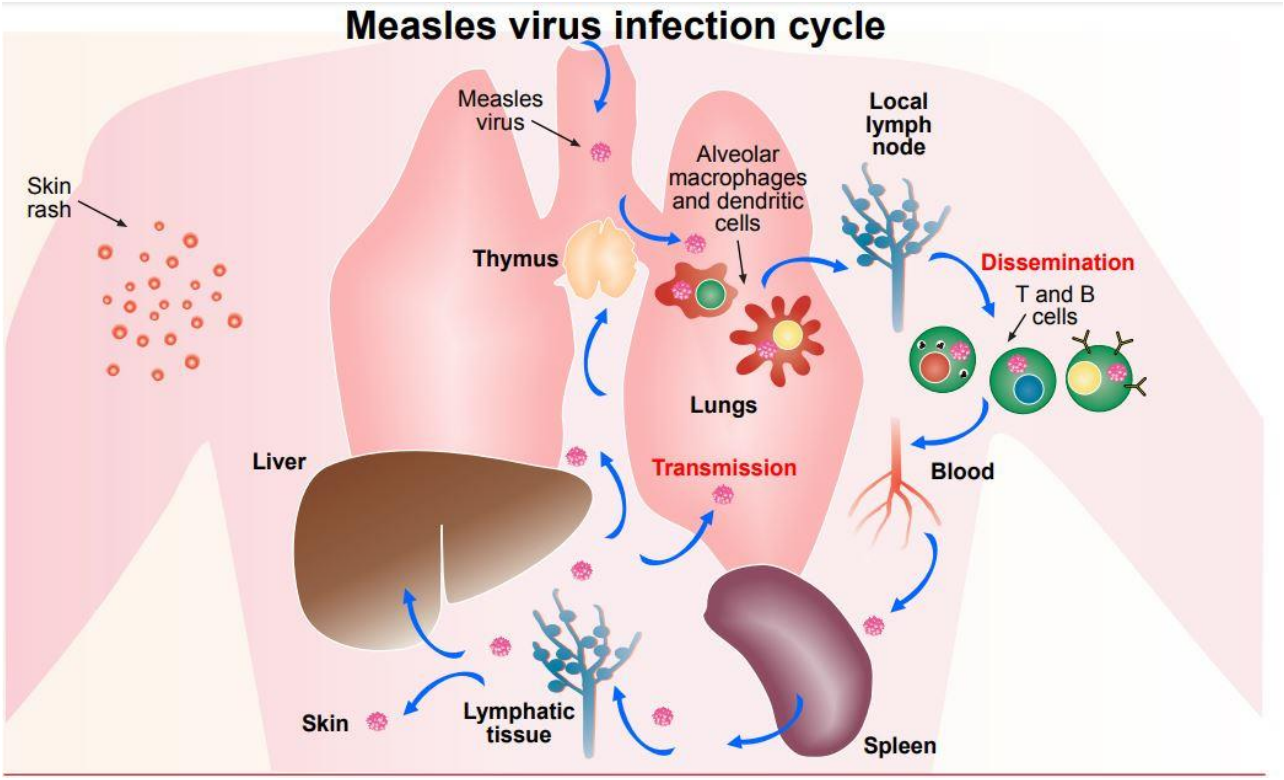
Pathogenesis: The infection is spread in saliva and secretions from the respiratory tract, and is acquired by the respiratory route, either by aerosol or hand contact. The incubation period is 14-21 days. Viraemia during the acute phase is followed by generalized spread to various organs, including the parotid gland. Virus is shed for several days before and after the first symptoms, not only from the respiratory tract but also in the urine. Mumps virus binds to sialic acid to enter the polarized epithelial cells in the upper respiratory tract from both sides.

2- Measles

Measles is a highly contagious infectious disease caused by measles virus. Symptoms usually develop 10–12 days after exposure to an infected person and last 7–10 days. Over 1 million mal-nutrient children die each year of measles in the developing world.

Measles target cells

The main target cells are immune cells such as T and B cells, macrophages and dendritic cells that express CD150 (or SLAM) which serves as an entry receptor. CD46 expressed on most cells can also be used by some wild-type strains. Measles virus infects epithelial cells using nectin-4.Measles virus can also penetrate the brain, but is usually controlled. Infection of pulmonary epithelial cells permits transmission to other hosts.



Symptoms of measles

The initial symptoms of measles develop around 10 days after you're infected.

These can include:

- cold-like symptoms, such as a runny nose, sneezing and a cough
- sore, red eyes that may be sensitive to light
- a high temperature (fever), which may reach around 40C
- small greyish-white spots on the inside of the cheeks

3- Para-influenza

The human parainfluenza viruses (HPIV) are the second most common causes of respiratory tract disease in infants and children. There are four types of HPIVs, known as HPIV-1, HPIV-2, HPIV-3 and HPIV-4. HPIV-1 and HPIV-2 may cause cold-like symptoms, along with croup (laryngotracheobronchitis) in children.

HPIV-3 is associated with bronchiolitis, bronchitis, and pneumonia. HPIV-4 is less common than the other types, and is known to cause mild to severe respiratory tract illnesses.

Symptoms of of human para-influenza viruses

While symptoms may vary child-to-child, the most common include:

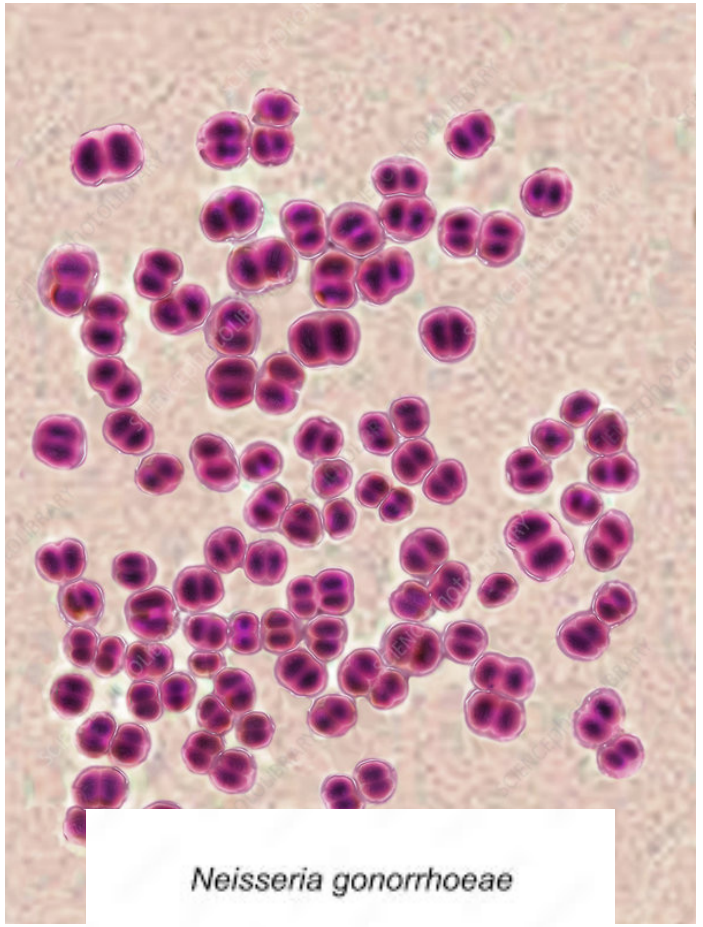
- runny nose
- redness or swelling of the eyes
- barky cough
- noisy, harsh breathing
- wheezing
- fever
- irritability
- decreased appetite
- vomiting
- diarrhea

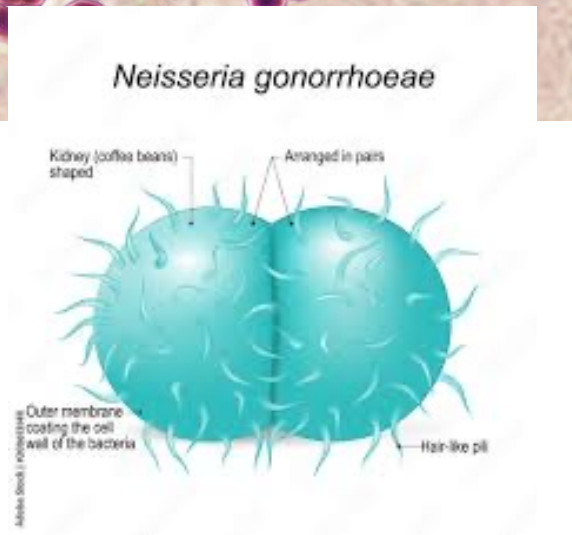
Neisseria

- ***Neisseria*** is a large genus of bacteria that colonize the mucosal surfaces of many animals. Of the 11 species that colonize humans, only two are pathogens, *N. meningitidis* and *N. gonorrhoeae*.
- The genus *Neisseria* is named after the German bacteriologist Albert Neisser, who in 1879 discovered *Neisseria gonorrhoeae*
- Species of this genus (family Neisseriaceae) of parasitic bacteria grow in pairs and occasionally tetrads, and thrive best at (37 °C) in the animal body or serum media.

The genus includes:

- *N. gonorrhoeae* (also called the gonococcus) causes gonorrhea.
- *N. meningitidis* (also called the meningococcus) is one of the most common causes of bacterial meningitis and the causative agent of meningococcal septicaemia.

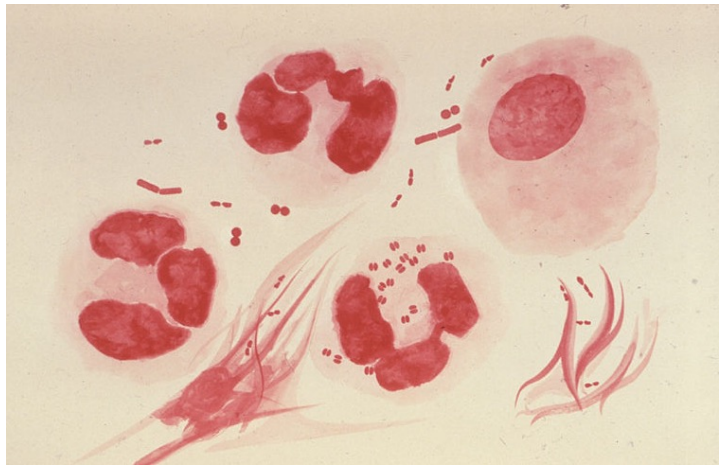




- *Neisseria* species are fastidious, Gram-negative cocci that require nutrient supplementation to grow in laboratory cultures. *Neisseria* spp. are intracellular and typically appear in pairs (diplococci), resembling the shape of coffee beans. *Nesseria* is non-spore-forming, capable of moving using twitching motility, and an obligate aerobe (requires oxygen to grow).

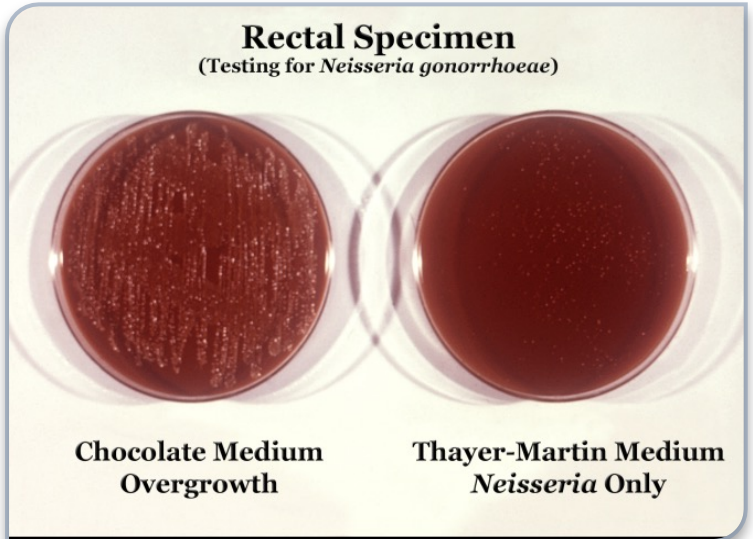
Neisseria gonorrhoeae

- Also known as ***gonococcus*** (singular), or ***gonococci*** (plural) is a species of Gram-negative diplococci bacteria .
- It causes the sexually transmitted genitourinary infection gonorrhea as well as other forms of gonococcal disease including disseminated gonococcemia, septic arthritis, and gonococcal ophthalmia neonatorum.



Culture and identification

- *N. gonorrhoeae* is usually isolated on Thayer-Martin agar (or VPN) agar in an environment enriched with 3-7% carbon dioxide. Thayer-Martin agar is a chocolate agar plate (heated blood agar) containing nutrients and antimicrobials (vancomycin, colistin, nystatin, and trimethoprim). This agar preparation facilitates the growth of *Neisseria* species while inhibiting the growth of contaminating bacteria and fungi. Martin Lewis and New York City agar are other types of selective chocolate agar commonly used for *Neisseria* growth.
- *N. gonorrhoeae* is oxidase positive and catalase positive (able to convert hydrogen peroxide to oxygen). When incubated with the carbohydrates lactose, maltose, sucrose, and glucose, *N. gonorrhoeae* will oxidize only the glucose.



Surface molecules

- On its surface, *N. gonorrhoeae* have hair-like pili, surface proteins with various functions, and sugars called lipooligosaccharides.
- Dynamic polymeric protein filaments called type IV pili allow *N. gonorrhoeae* to adhere to and move along surfaces.
- To enter the host the bacteria uses the pili to adhere to and penetrate mucosal surfaces. The pili are a necessary virulence factor for *N. gonorrhoeae*; without them, the bacterium is unable to cause infection.
- The adhesive functions of the gonococcal pilus play a role in microcolony aggregation and biofilm formation.
- Surface proteins called Opa proteins can be used to bind to receptors on immune cells and prevent an immune response.
- Lipooligosaccharide (LOS) is a low-weight version of lipopolysaccharide that present on the surfaces of most other Gram-negative bacteria.
- The root "oligo" refers to the fact that it is a few sugars shorter than the typical lipopolysaccharide.
- As an endotoxin, LOS provokes inflammation. The shedding of LOS by the bacteria is responsible for local injury in, for example, pelvic inflammatory disease.

Infection and Disease

- After gonococci attach and invade the host epithelial cells, they land in the submucosa, where neutrophils promptly consume them. The pili and Opa proteins on the surface may interfere with phagocytosis, but most gonococci end up in neutrophils.
- The exudates from infected individuals contain many neutrophils with ingested gonococci. Neutrophils release an oxidative burst of reactive oxygen species in their phagosomes to kill the gonococci. However, a significant fraction of the gonococci can resist killing through the action of their catalase· which breaks down reactive oxygen species and is able to reproduce within the neutrophil phagosomes.
- the bacterial RecA protein, which mediates repair of DNA damage, plays an important role in gonococcal survival. *N. gonorrhoeae* may replace DNA damaged in neutrophil phagosomes with DNA from neighboring gonococci.
- *N. gonorrhoeae* exhibits antigenic variation through recombination of its pili and surface proteins that interact with the immune system.

transmission

- Sexual transmission is possible and Perinatal transmission may occur during childbirth, and may be prevented by antibiotic treatment of the mother before birth and the application of antibiotic eye gel on the eyes of the newborn.
- After an episode of gonococcal infection, infected persons do not develop immunity to future infections. Reinfection is possible due to *N. gonorrhoeae's* ability to evade the immune system by varying its surface proteins.
- *N. gonorrhoeae* can cause infection of the genitals, throat, and eyes. Asymptomatic infection is common in males and females. Untreated infection may spread to the rest of the body (disseminated gonorrhea infection), especially the joints (septic arthritis). Untreated infection in women may cause pelvic inflammatory disease and possible infertility due to the resulting scarring.

Symptoms

- Symptoms of infection with *N. gonorrhoeae* differ depending on the site of infection and many infections are asymptomatic .
- In symptomatic men, the primary symptom of genitourinary infection is urethritis – burning with urination (dysuria), increased urge to urinate, and a pus-like (purulent) discharge coming with urine .
- If untreated, scarring of the urethra may result in difficulty urinating. Infection may spread from the urethra to nearby structures. Men who have had a gonorrhea infection have a significantly increased risk of having prostate cancer.
- In symptomatic women, the primary symptoms of genitourinary infection are increased vaginal discharge, burning with urination (dysuria), increased urge to urinate.
- Pelvic inflammatory disease results if *N. gonorrhoeae* ascends into the pelvic peritoneum (via the cervix, endometrium, and fallopian tubes). The resulting inflammation and scarring of the fallopian tubes can lead to infertility and increased risk of ectopic pregnancy.
- *N. gonorrhoeae* may cause (pharyngitis) or (proctitis).

- In perinatal infection, the primary manifestation is infection of the eye (neonatal conjunctivitis or ophthalmia neonatorum) when the newborn is exposed to *N. gonorrhoeae* in the birth canal. The eye infection can lead to corneal scarring or perforation, ultimately resulting in blindness.
- Gonococcal ophthalmia neonatorum, once common in newborns, is prevented by the application of erythromycin (antibiotic) gel to the eyes of babies at birth as a public health measure.
- Disseminated gonococcal infections can occur when *N. gonorrhoeae* enters the bloodstream, often spreading to the joints and causing a rash (dermatitis-arthritis syndrome).
- Diagnosis is through culture, Gram stain, or polymerase chain reaction testing of a urine sample, urethral swab, or cervical swab.

Treatment of gonococcal infection

- The current recommended treatment is a dual antibiotic therapy. This includes an injected single dose of ceftriaxone (a third-generation cephalosporin) along with azithromycin administered orally. Azithromycin is preferred for additional coverage of gonorrhea that may be resistant to cephalosporins.

***Neisseria meningitidis*,**

- **Meningococcus**, can cause meningitis and other forms of meningococcal disease such as meningococcemia, a life-threatening sepsis.
- About 10% of adults are carriers of the bacteria in their nasopharynx. As an exclusively human pathogen it is the main cause of bacterial meningitis in children and young adults, causing developmental impairment and death in about 10% of cases.
- *N. meningitidis* is spread through saliva and respiratory secretions during coughing, sneezing, kissing, chewing on toys and even through sharing a source of fresh water.

Virulence

- Lipooligosaccharide (LOS) is a component of the outer membrane of *N. meningitidis*.
- This acts as an endotoxin and is responsible for septic shock and hemorrhage due to the destruction of red blood cells.
- Other virulence factors include a polysaccharide capsule which prevents host phagocytosis and aids in evasion of the host immune response;
- fimbriae mediate attachment of the bacterium to the epithelial cells of the nasopharynx. It infects the cell by sticking to it mainly with long thin extensions called pili and the surface-exposed proteins Opa and Opc.
- Meningococci produce an IgA protease, an enzyme that cleaves IgA class antibodies and thus allows the bacteria to evade a subclass of the humoral immune system.
- A hypervirulent strain was discovered in China.

Treatment

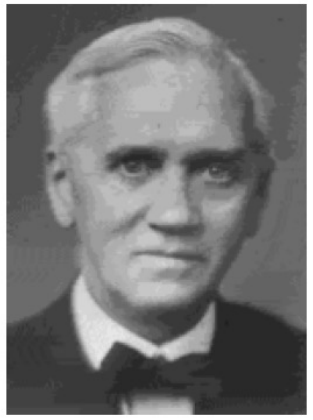
- Persons with confirmed *N. meningitidis* infection should be hospitalized immediately for treatment with antibiotics. Because meningococcal disease can disseminate very rapidly, a single dose of intramuscular antibiotic is often given at the earliest possible opportunity, even before hospitalization, if disease symptoms look suspicious enough.
- Third-generation cephalosporin antibiotics (i.e. cefotaxime, ceftriaxone) should be used to treat a suspected or culture-proven meningococcal infection before antibiotic susceptibility results are available.

Vaccine

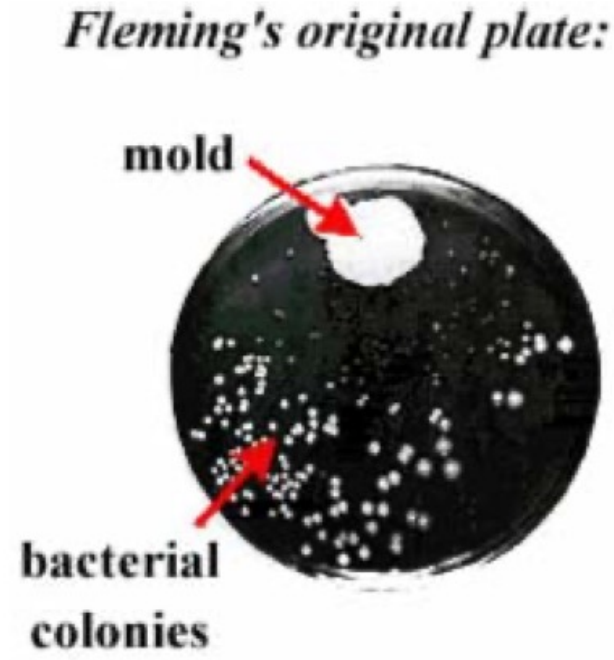
- Diseases caused by *N. meningitidis* and *N. gonorrhoeae* are significant health problems worldwide, the control of which is largely dependent on the availability and widespread use of comprehensive meningococcal and gonococcal vaccines.
- Development of neisserial vaccines has been challenging due to the nature of these organisms, in particular the heterogeneity, variability and/or poor immunogenicity of their outer surface components.
- Currently, serogroup A, B, C, Y, and W-135 meningococcal infections can be prevented by vaccines. However, the prospect of developing a gonococcal vaccine is still remote

Antibiotics

Antibiotic: Substance produced by a microorganism [or a similar product produced wholly (synthetic) or partially (semi- synthetic) by chemical synthesis] that is capable, in low concentrations, of inhibiting the growth of or killing other microoganisms.



Alexander Fleming
Nobel Prize: 1945
Penicillin



- Drugs have been used for the treatment of infectious diseases since the 17th century (eg, quinine for malaria, emetine for amebiasis); however, chemotherapy as a science began in the first decade of the 20th century with understanding of the principles of:

1. selective toxicity,
2. the specific chemical relation- ships between microbial pathogens and drugs,
3. the development of drug resistance,
4. and the role of combined therapy.

MECHANISMS OF ACTION OF ANTIMICROBIAL DRUGS

- Antimicrobial drugs act in one of several ways: by selective toxicity, by inhibition of cell membrane synthesis and function, by inhibition of protein synthesis, or by inhibition of nucleic acid synthesis.

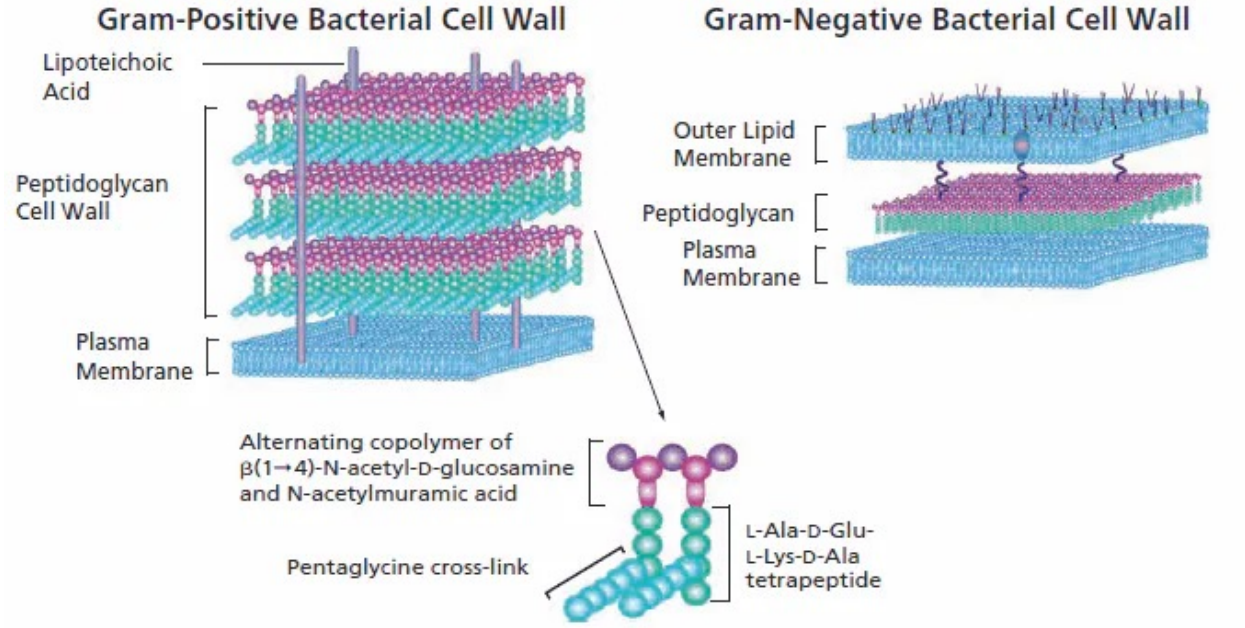
SELECTIVE TOXICITY

- An ideal antimicrobial agent exhibits selective toxicity, which means that the drug is harmful to a pathogen without being harmful to the host. Often, selective toxicity is relative rather than absolute; this implies that a drug in a concentration tolerated by the host may damage an infecting microorganism.
- Selective toxicity may be a function of a specific receptor required for drug attachment, or it may depend on the inhibition of biochemical events essential to the pathogen but not to the host. The mechanisms of action of antimicrobial drugs can be discussed under four headings:

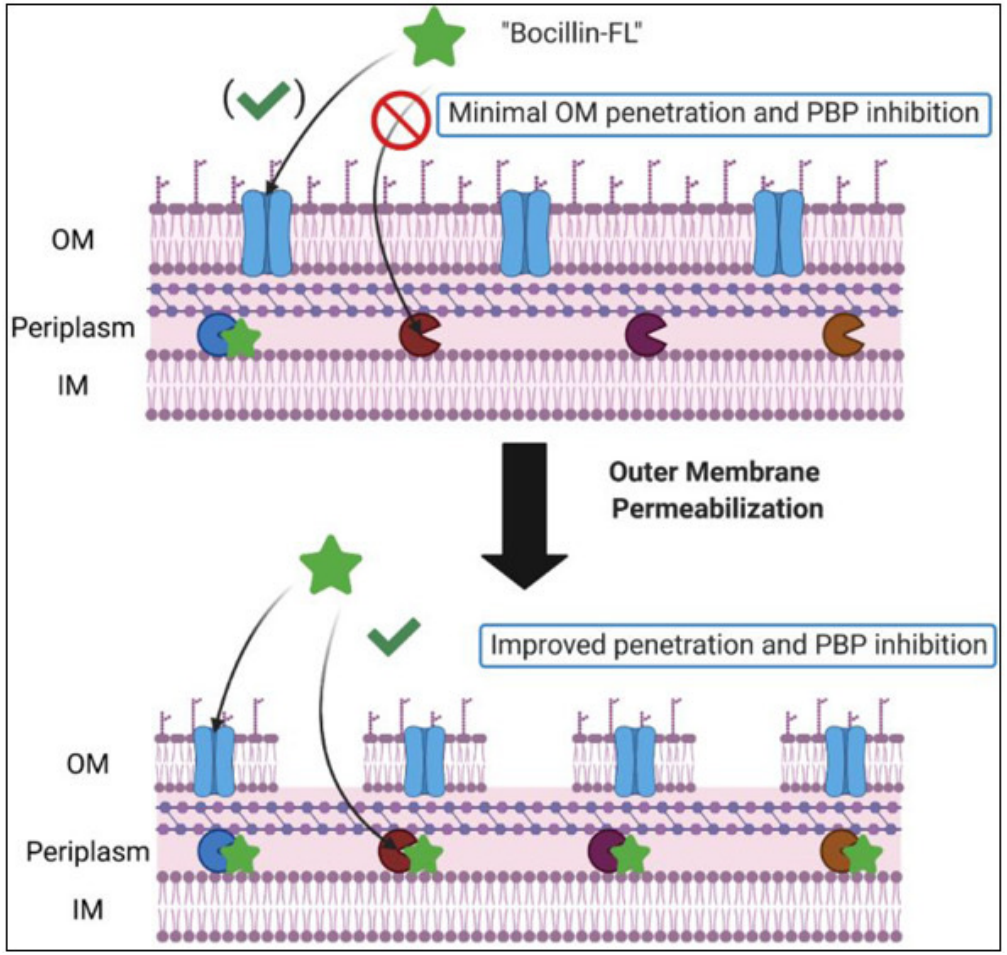
1. Inhibition of cell wall synthesis
2. Inhibition of cell membrane function
3. Inhibition of protein synthesis (ie, inhibition of translation and transcription of genetic material)
4. Inhibition of nucleic acid synthesis

INHIBITION OF CELL WALL SYNTHESIS

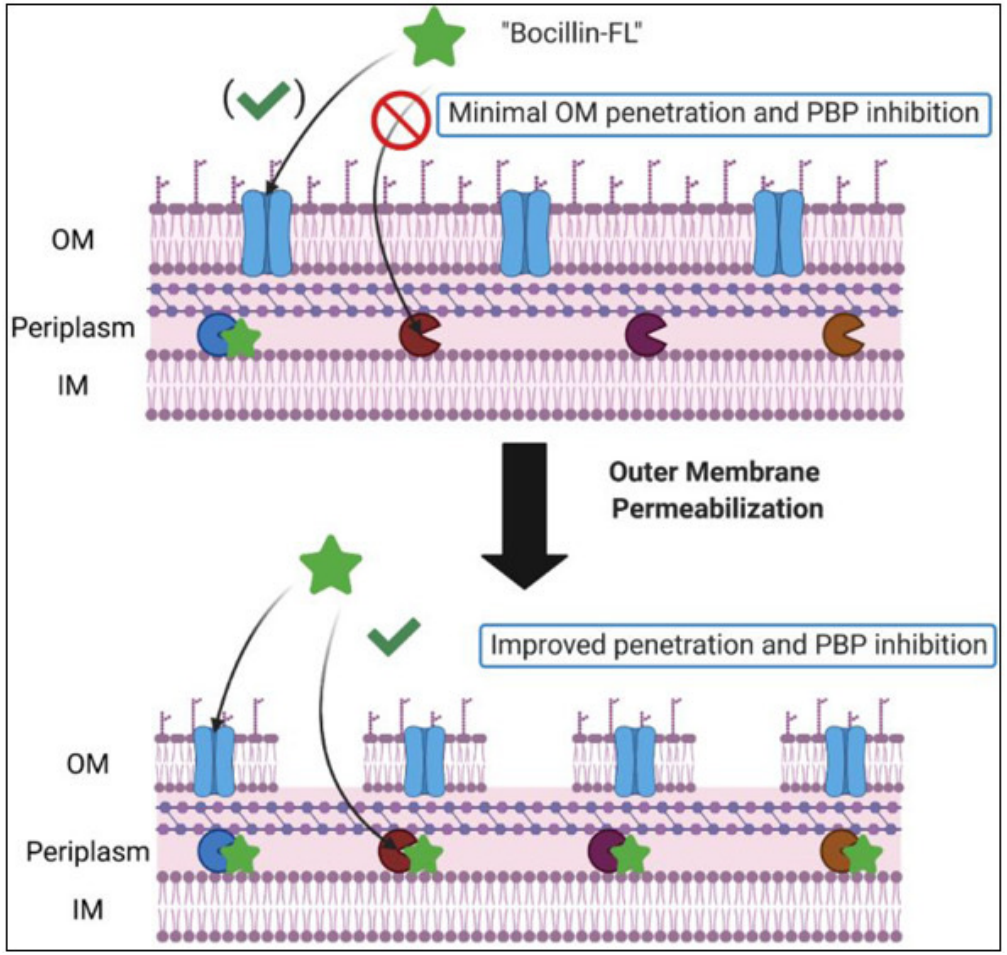
- The cell wall contains a chemically distinct complex polymer (“peptidoglycan”) consisting of polysaccharides and a highly cross-linked polypeptide. The polysaccharides regularly contain the amino sugars *N*-acetylglucosamine and acetylmuramic acid. The latter is found only in bacteria. To the amino sugars are attached short peptide chains. The final rigidity of the cell wall is imparted by cross-linking of the peptide chains (eg, through pentaglycine bonds) as a result of transpeptidation reactions carried out by several enzymes. The peptidoglycan layer is much thicker in the cell wall of gram-positive than of gram-negative bacteria.



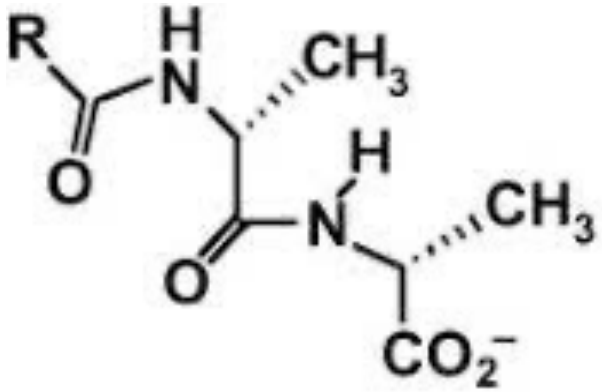
- All β-lactam drugs are selective inhibitors of bacterial cell wall synthesis and therefore active against growing bacteria.
- The initial step in drug action consists of binding of the drug to cell receptors **(penicillin-binding proteins [PBPs])**. There are at least six different PBPs (molecular weight [MW], 40–120 kilodaltons [kD]), some of which are transpeptidation enzymes. Different receptors have different affinities for a drug, and each may mediate a different effect.
- For example, attachment of penicillin to one PBP may result chiefly in abnormal elongation of the cell, but attachment to another PBP may lead to a defect in the periphery of the cell wall with resulting cell lysis.
- PBPs are under chromosomal control, and mutations may alter their number or their affinity for β-lactam drugs.



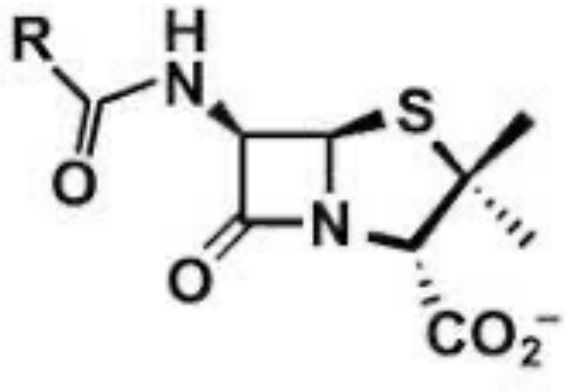
- After a β-lactam drug has attached to one or more receptors, the transpeptidation reaction is inhibited, and peptidoglycan synthesis is blocked.
- The next step probably involves removal or inactivation of an inhibitor of autolytic enzymes in the cell wall. This activates the lytic enzyme and results in lysis if the environment is isotonic.



- The inhibition of the transpeptidation enzymes by penicillins and cephalosporins may be attributable to a structural similarity of these drugs to acyl-d-alanyl-d-alanine. The transpeptidation reaction involves loss of a d-alanine from the pentapeptide.

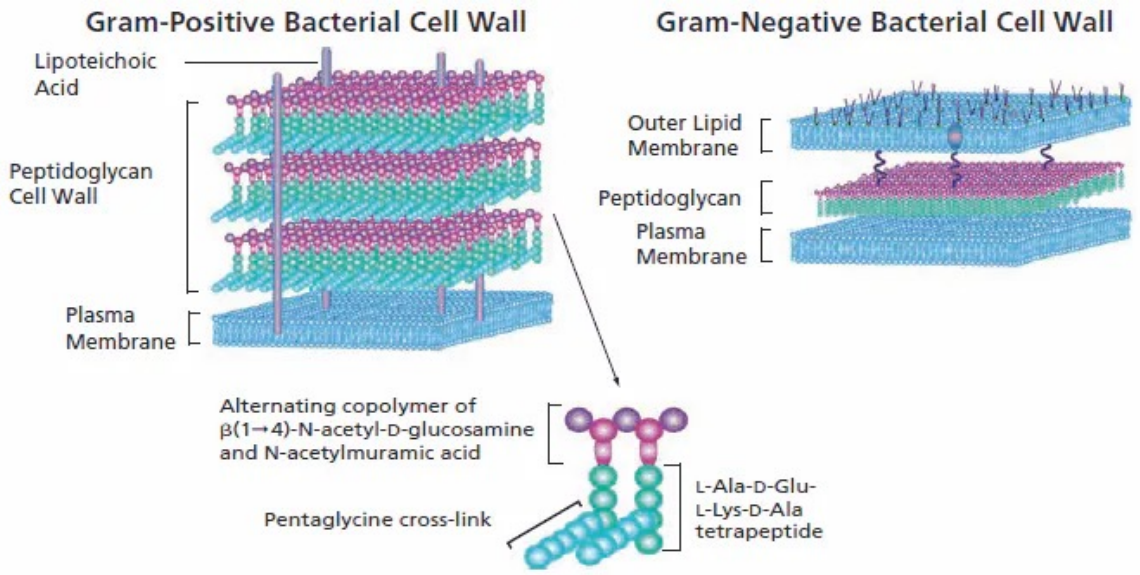


acyl-D-Ala-D-Ala

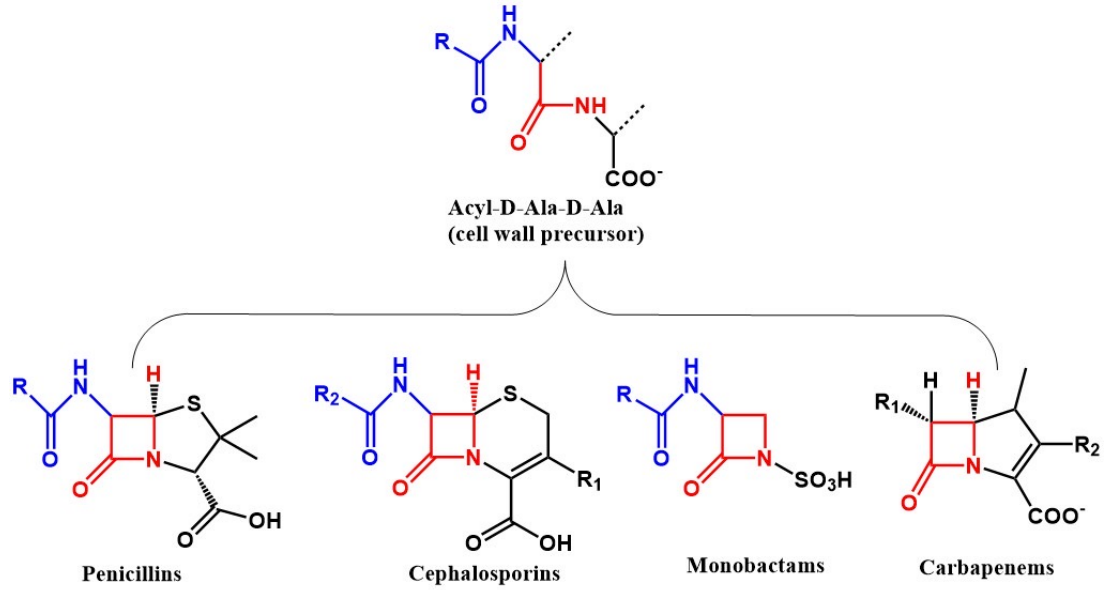


a penicillin

- The remarkable lack of toxicity of β-lactam drugs to mammalian cells must be attributed to the absence in animal cells of a bacterial type cell wall with its peptidoglycan.
- The difference in susceptibility of gram-positive and gram- negative bacteria to various penicillins or cephalosporins probably depends on structural differences in their cell walls that determine penetration, binding, and activity of the drugs.



- Resistance to penicillins may be determined by the organism's production of penicillin-destroying enzymes (β-lactamases). The **β-lactamases** open the β-lactam ring of penicillins and cephalosporins and abolish their antimicrobial activity. β-Lactamases have been described for many species of gram-positive and gram-negative bacteria. Some β-lactamases are plasmid mediated (eg, penicillinase of *Staphylococcus aureus*), and others are chromosomally mediated (eg, many species of gram-negative bacteria).



Core structure of beta-lactam antibiotics

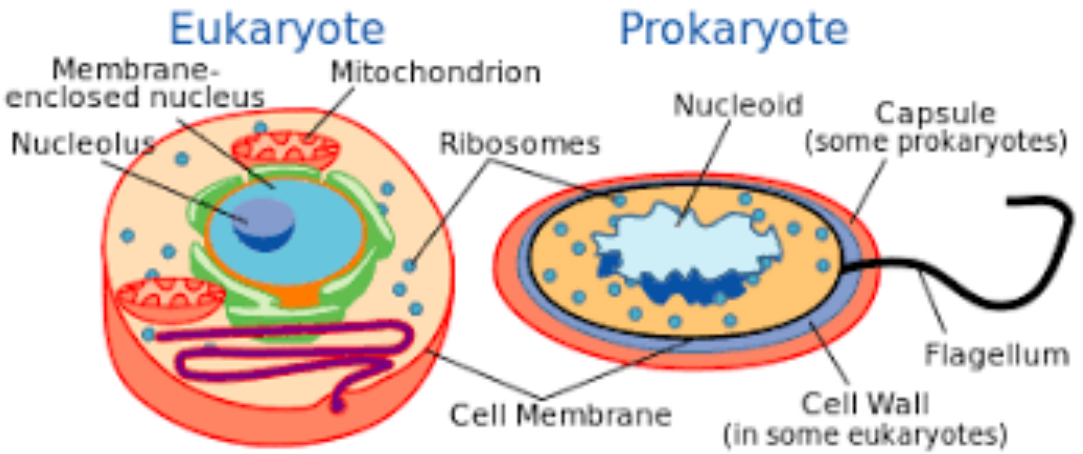
- There is one group of β-lactamases that is occasionally found in certain species of gram-negative bacilli, usually *Klebsiella pneumoniae* and *Escherichia coli*. These enzymes are termed **extended-spectrum β-lactamases (ESBLs)** because they confer upon the bacteria the additional ability to hydrolyze the β-lactam rings of cefotaxime, ceftazidime, or aztreonam.
- Of most concern is the emergence of ***K pneumoniae* carbapenemases (KPC)**, which are ESBL-type enzymes that confer resistance to third- and fourth-generation cephalosporins and carbapenems.
- This resistance mechanism is plasmid mediated and has spread nosocomially among many hospitals throughout the United States and other countries.
- Although they were discovered in the mid-1960s, global spread of genes encoding metallo-β-lactamases has facilitated spread of these broad-range, inhibitor-resistant enzymes among many gram-negative pathogens.
- This has ushered in an era of widespread dissemination of carbapenem-resistant *Enterobacteriaceae* possessing the VIM-type (Verona integron-encoded metallo-β-lactamase) and NDM-type (New Delhi metallo-β-lactamase) of these enzymes.

- VIM- type enzymes first appeared in *Pseudomonas aeruginosa* and *Acinetobacter baumannii*, but within the past decade, they have spread to *Enterobacteriaceae*. There are more than 20 types, and they are most prevalent in Europe, the Middle East, and Asia.

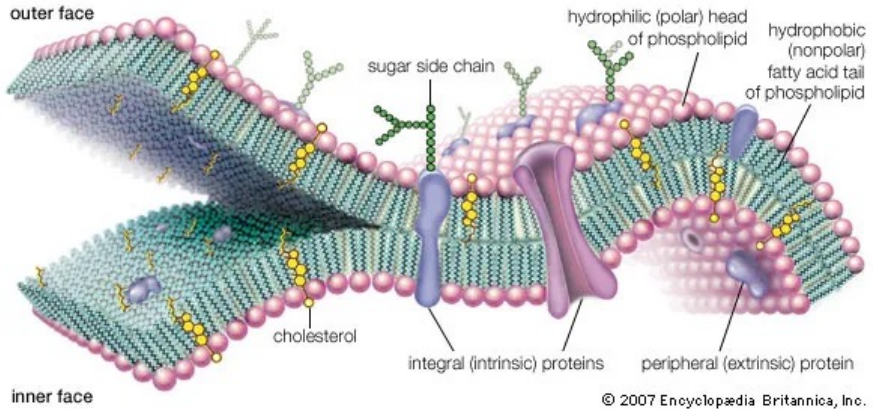
- NDM-1 is relatively new, having been described first in a *K pneumoniae* strain in Sweden from a patient who had travelled to India.
- Because these organisms often contain genes that encode resistance to other classes of antimicrobials, such as fluoroquinolones and aminoglycosides, options for treatment are very limited to agents such colistin.
- Therefore, such patients are often placed on maximum infection control precautions to prevent spread to other patients within hospital environments.

INHIBITION/ALTERATION OF CELL MEMBRANE FUNCTION

- The cytoplasms of all living cells are bounded by the cytoplasmic membrane, which serves as a selective permeability barrier and carries out active transport functions and thus controls the internal composition of the cell.
- If the functional integrity of the cytoplasmic membrane is disrupted, macromolecules and ions escape from the cell, and cell damage or death ensues.

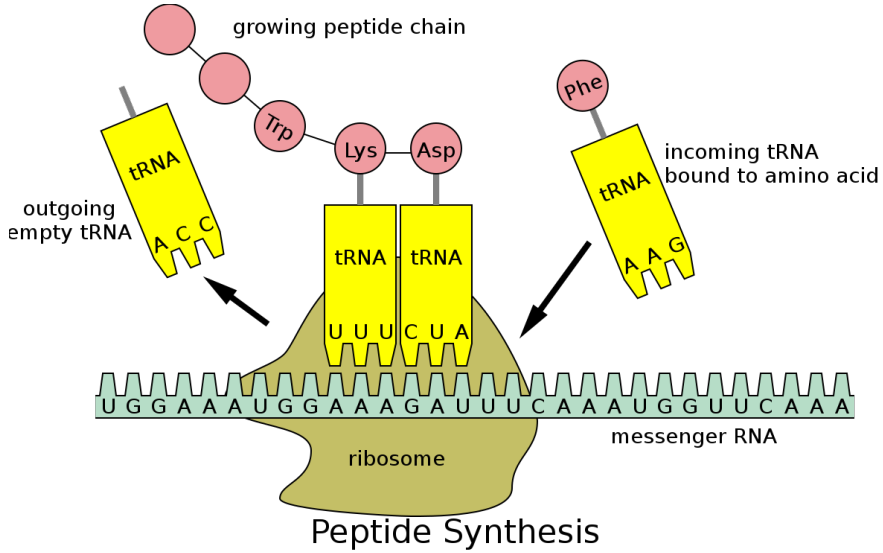


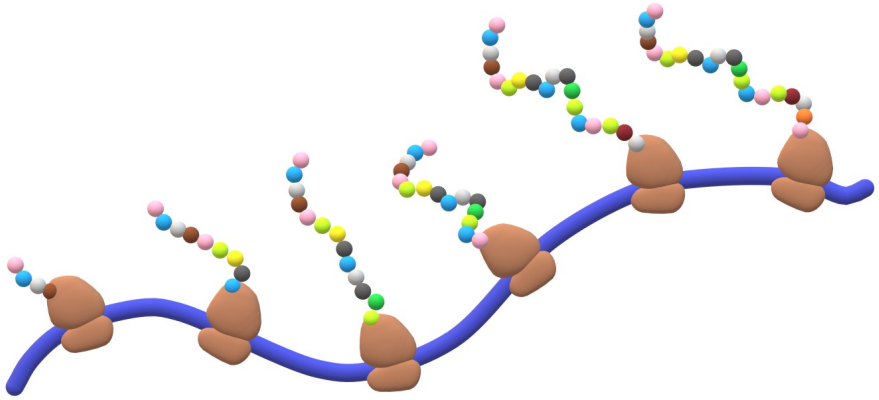
- Detergents, which contain lipophilic and hydrophilic groups, disrupt cytoplasmic membranes and kill the cell.
- One class of antibiotics, the polymyxins, consists of detergent-like cyclic peptides that selectively damage membranes containing phosphatidylethanolamine, a major component of bacterial membranes.
- A number of antibiotics specifically interfere with biosynthetic functions of the cytoplasmic membranes (eg, nalidixic acid and novobiocin inhibit DNA synthesis, and novobiocin also inhibits teichoic acid synthesis).
- A third class of membrane-active agents the ionophores, compounds that permit rapid diffusion of specific cations through the membrane. Valinomycin, for example, specifically mediates the passage of potassium ions.
- Ionophores can kill cells by discharging the membrane potential, which is essential for oxidative phosphorylation, as well as for other membrane-mediated processes; they are not selective for bacteria but act on the membranes of all cells.
- Daptomycin is a cyclic 13-member lipopeptide antibiotic that is rapidly bactericidal by binding to the cell membrane in a calcium ion–dependent manner, causing depolarization of bacterial membrane potential. This leads to intracellular potassium release that causes cell death.



INHIBITION OF PROTEIN SYNTHESIS

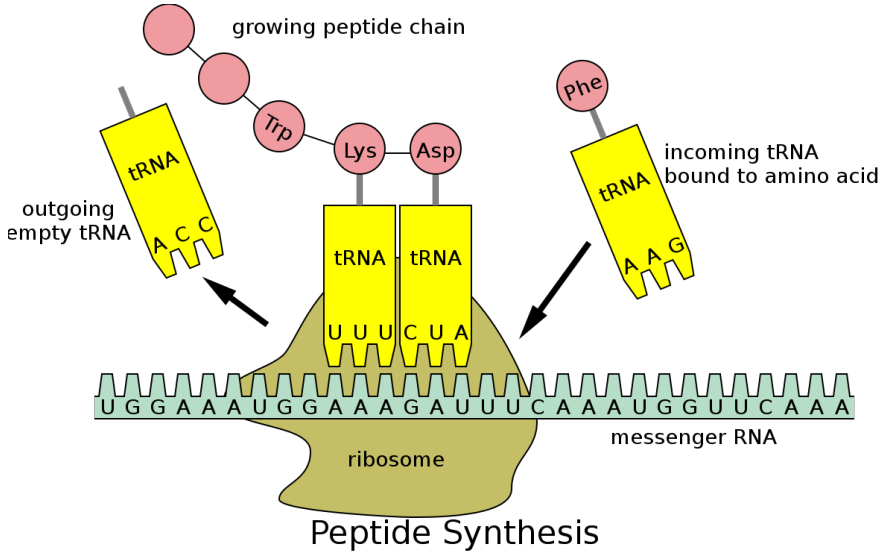
- whereas bacteria have 70S ribosomes, mammalian cells have 80S ribosomes. The subunits of each type of ribosome, their chemical composition, and their functional specificities are sufficiently different to explain why antimicrobial drugs can inhibit protein synthesis in bacterial ribosomes without having a major effect on mammalian ribosomes.
- In normal microbial protein synthesis, the mRNA message is simultaneously “read” by several ribosomes that are strung out along the mRNA strand. These are called **polysomes**.



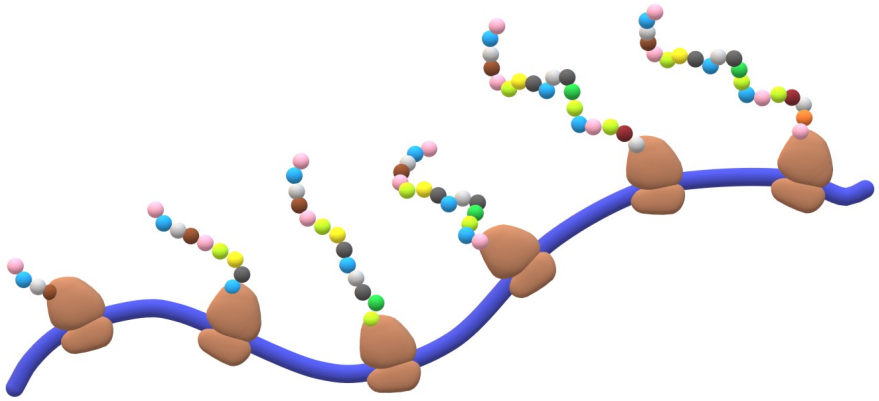


Aminoglycosides

- The first step is the attachment of the amino-glycoside to a specific receptor protein (P 12 in the case of streptomycin) on the 30S subunit of the microbial ribosome.
- Second, the aminoglycoside blocks the normal activity of the “initiation complex” of peptide formation (mRNA + formyl methionine + tRNA).
- Third, the mRNA message is misread on the “recognition region” of the ribosome; consequently, the wrong amino acid is inserted into the peptide, resulting in a nonfunctional protein.
- Fourth, aminoglycoside attachment results in the breakup of polysomes and their separation into **monosomes** incapable of protein synthesis.
- These activities occur more or less simultaneously, and the overall effect is usually an irreversible event—killing of the bacterium.



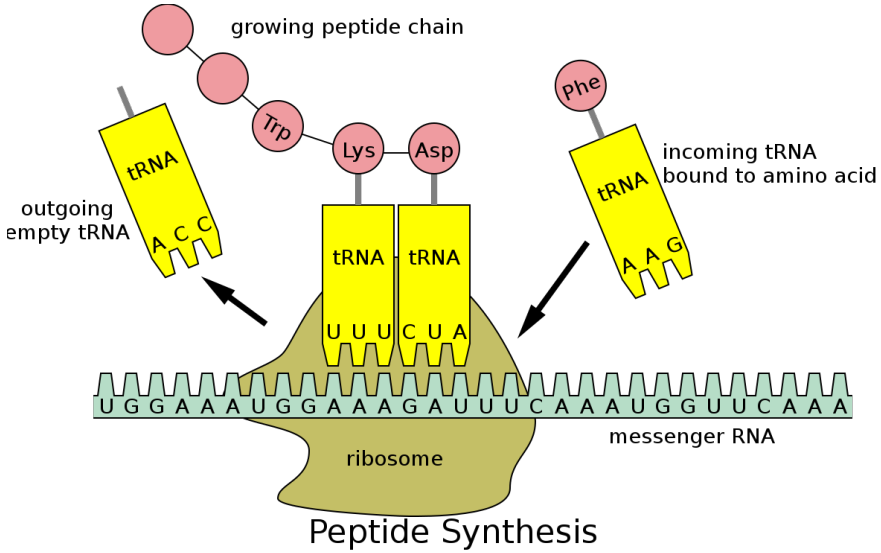
Peptide Synthesis



- Chromosomal resistance of microbes to aminoglycosides principally depends on the lack of a specific protein receptor (modification of the target site caused by mutations) on the 30S subunit of the ribosome.
- Plasmid-dependent resistance to aminoglycosides depends on the production by the micro- organism of adenylating, phosphorylating, or acetylating enzymes that destroy the drugs (most common mechanism).
- A third type of resistance consists of a “permeability defect,” an outer membrane change that reduces active transport of the aminoglycoside into the cell so the drug cannot reach the ribosome. Often this is plasmid mediated.

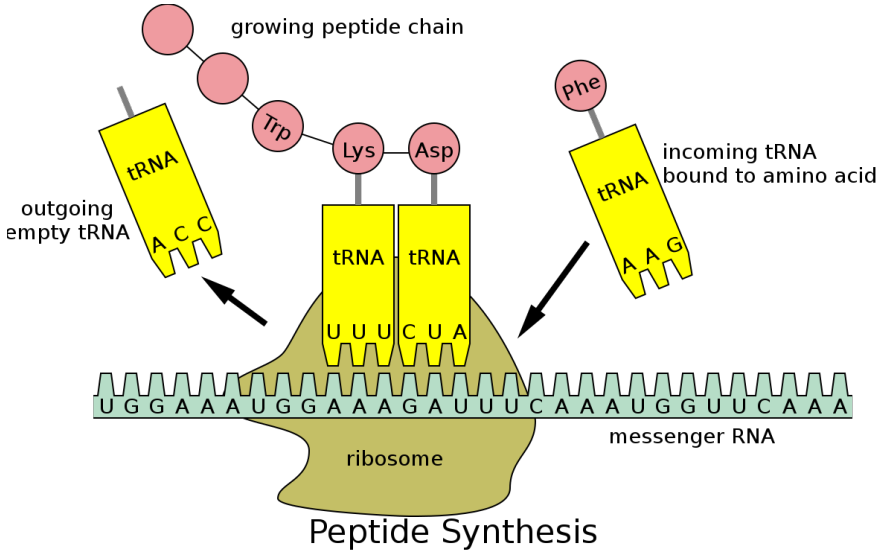
Macrolides, Azalides, and Ketolides

- These drugs (erythromycins, azithromycin, clarithromycin, and roxithromycin and the ketolide telithromycin) bind to the 50S subunit of the ribosome, and the binding site is domain V of the 23S rRNA.
- They may interfere with formation of initiation complexes for peptide chain synthesis or may interfere with aminoacyl translocation reactions.
- Some macrolide-resistant bacteria lack the proper receptor on the ribosome (through methylation of the 23S rRNA target site).
- The *erm* (erythromycin ribosome methylation) genes that encode this mechanism may be under plasmid or chromosomal control. They may be expressed constitutively or may be induced by subinhibitory concentrations of macrolides.



Tetracyclines

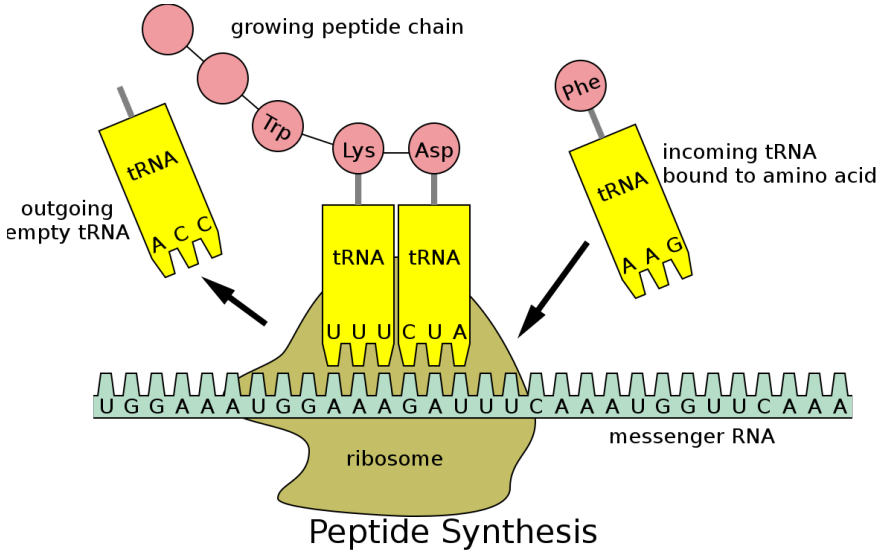
- Tetracyclines bind reversibly to the 30S subunit of microbial ribosomes.
- They inhibit protein synthesis by blocking the attachment of charged aminoacyl-tRNA.
- Thus, they prevent introduction of new amino acids to the nascent peptide chain.
- The action is usually inhibitory and reversible upon withdrawal of the drug.
- Resistance to tetracyclines occurs by multiple mechanisms—efflux, ribosomal protection proteins, and chemical modification, among others.



Peptide Synthesis

Chloramphenicol

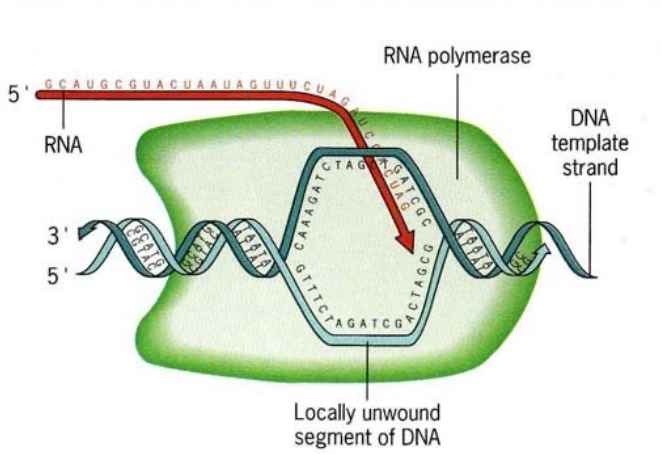
- Chloramphenicol binds to the 50S subunit of the 70S bacterial ribosome.
- It interferes with the binding of new amino acids to the nascent peptide chain, largely because chloramphenicol inhibits peptidyl transferase.
- Chloramphenicol is mainly bacteriostatic, and growth of microorganisms resumes when the drug is withdrawn.
- Microorganisms resistant to chloramphenicol usually produce the chloramphenicol acetyltransferases, which destroys drug activity.
- The production of this enzyme is usually under the control of plasmid-mediated resistance genes called *cat* genes.
- Other mechanisms of resistance include efflux pumps and decreased membrane permeability.

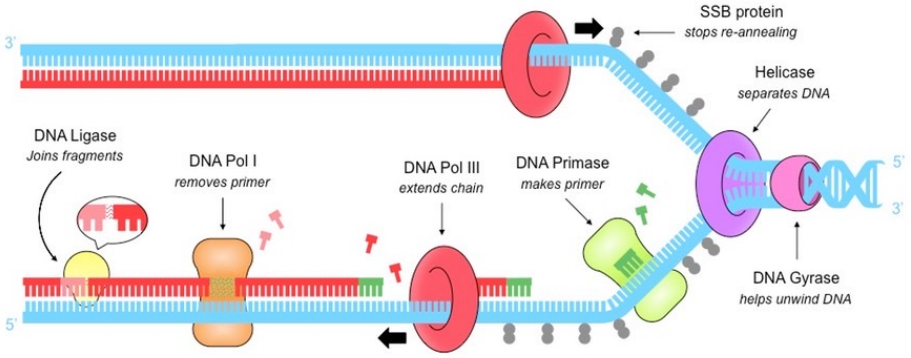


Peptide Synthesis

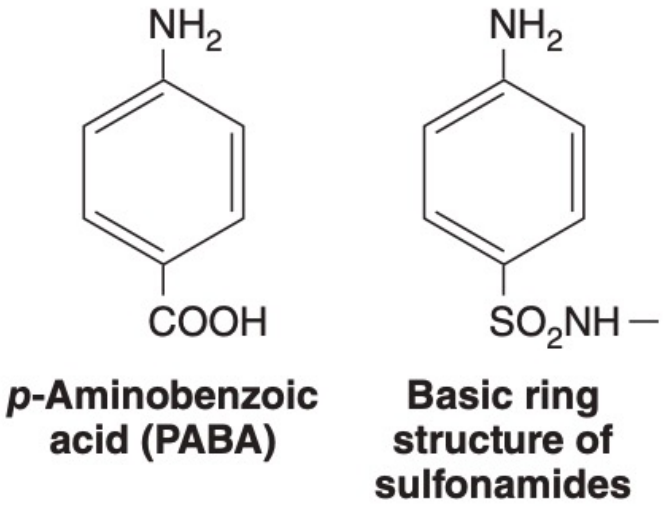
INHIBITION OF NUCLEIC ACID SYNTHESIS

- Rifampin inhibits bacterial growth by binding strongly to the DNA-dependent RNA polymerase of bacteria.
- Thus, it inhibits bacterial RNA synthesis. Rifampin resistance results from a change in RNA polymerase because of a chromosomal mutation that occurs with high frequency.
- The mechanism of rifampin action on viruses is different. It blocks a late stage in the assembly of poxviruses.
- All quinolones and fluoroquinolones inhibit microbial DNA synthesis by blocking DNA gyrases, topoisomerase enzymes that play key roles in DNA replication and repair.





- For many microorganisms, *p*-aminobenzoic acid (PABA) is an essential metabolite.
- The specific mode of action of PABA involves an adenosine triphosphate (ATP)–dependent condensation of a pteridine with PABA to yield dihydropteroic acid, which is subsequently converted to folic acid.
- PABA is involved in the synthesis of folic acid, an important precursor to the synthesis of nucleic acids. Sulfonamides are structural analogs of PABA and inhibit dihydropteroate synthetase.
- Sulfonamides can enter into the reaction in place of PABA and compete for the active center of the enzyme.
- As a result, nonfunctional analogs of folic acid are formed, preventing further growth of the bacterial cell.
- The inhibiting action of sulfonamides on bacterial growth can be counteracted by an excess of PABA in the environment (competitive inhibition). Animal cells cannot synthesize folic acid and must depend on exogenous sources.



p-Aminobenzoic acid (PABA)

Basic ring structure of sulfonamides

- Trimethoprim (3,4,5-trimethoxybenzylpyrimidine) inhibits dihydrofolic acid reductase 50,000 times more efficiently in bacteria than in mammalian cells.
- This enzyme reduces dihydrofolic to tetrahydrofolic acid, a stage in the sequence leading to the synthesis of purines and ultimately of DNA.
- Sulfonamides and trimethoprim if used together, they produce sequential blocking, resulting in a marked enhancement (synergism) of activity.
- Such mixtures of sulfonamide (five parts) plus trimethoprim (one part) have been used in the treatment of pneumocystis pneumonia, malaria, shigella enteritis, systemic salmonella infections, urinary tract infections, and many others.

Endodontic Microbiology

Microbial of apical periodontitis

Apical periodontitis is an inflammatory disease of microbial etiology primarily caused by infection of the root canal system. Endodontic infections usually develop after pulpal necrosis. Although fungi and most recently archaea and viruses have been found in endodontic infection, bacteria are the major microorganisms implicated in the etiology of the apical periodontitis. Bacteria colonizing the root canal system contact the periradicular tissues via apical and lateral foramina. As a consequence of the encounter between the bacteria and the host defences, inflammatory changes take place in the periradicular tissue and give rise to development of apical periodontitis.

The ultimate goal of the endodontic treatment is either to prevent the development of apical periodontitis or to create adequate conditions for periradicular tissue healing.

Routes of root canal infection

Under normal conditions, the dental pulp and dentin are sterile and isolated from oral microorganisms by overlying enamel and cementum. There are situations in which the integrity of these protective layers is breached (e.g., as a result of caries, trauma-induced fractures and cracks or restorative procedures) or naturally absent (e.g., because of gap in the cementoenamel junction at the cervical root service). The main portals of the pulp infection are dentinal tubules, direct pulp exposure, periodontal disease, and anachoresis.

Dentinal tubules

Whenever dentin is exposed, the pulp is put at risk for infection as a consequence of the permeability of normal dentin dictated by its tubular structure. Dentin permeability is increased near the pulp because of the larger diameter and higher density of tubules. Exposed dentin can challenge by microorganisms present in carious lesions, in saliva bathing the exposure area, or in dental plaque formed onto the exposed area.

Direct pulp exposure

Direct exposure of the dental pulp to the oral cavity is the most obvious route of endodontic infection. Caries is the most common cause of pulpal exposure, but microorganisms may also reach the pulp via direct pulp exposure as a result of iatrogenic restorative procedures or trauma. The exposed pulp tissue develops

direct contact with oral microorganisms from carious lesions, saliva, or plaque accumulated onto the exposure surface.

Periodontal disease

Microorganisms in sub-gingival biofilms associated with periodontal disease could reach the pulp by the same pathways that intercanal microorganisms reach the periodontium and thereby could exert harmful effects on the pulp. Nevertheless, it has been demonstrated that although degenerative and inflammatory changes of different degree may occur in the pulp of teeth with associated periodontal disease, pulpal necrosis as a consequence of periodontal disease only develops if the periodontal pocket reach the apical foramen, lead to irreversible damage to the main blood vessels that penetrate through this foramen.

Anachoresis

Anachoresis is a process by which microorganisms are transported in the blood or lymph to an area of tissue damage, where they leave the vessel, enter the damaged tissue, and establish an infection.

Type of endodontic infections

Endodontic infection can be classified according to the anatomical location (intraradicular or extraradicular). Intraradicular infections can be subdivided into three categories: primary, secondary, or persistent infection, established themselves within the root canal. The composition of microbiota may vary depending on the different forms of apical periodontitis.

Intraradicular infection

Microorganisms colonizing the root canal system cause intraradicular infection, which can classified as primary, secondary, or persistent.

Primary intraradicular infection

Microorganisms that initially invade and colonize the necrotic pulp tissue cause primary intraradicular infection. It has also been referred to as initial infection or “virgin” infection.

Primary infections are characterized by a mixed consortium composed of 10 to 30 bacterial species and 10^3 to 10^8 bacterial cells per canal. The involved microorganisms is dominated by anaerobic bacteria, but some facultative or microaerophillic species can also commonly found in primary intraradicular infections.

Secondary Intraradicular infection

Microorganisms that were not present in the primary infection but that were introduced into the root canal system at some time after professional intervention cause secondary intraradicular infection. The entry can be during treatment, between appointments, or even after root canal filling. Species involved can be oral or non- oral microorganisms, depending on the cause of infection. The main causes of microbial introduction in the canal during treatment include remnants of dental plaque, calculus, or caries on the tooth crown; leaking rubber dam; or contamination of endodontic instrument, irrigating solution, or other intra- canal medications. Microorganisms can enter the root canal system between appointments by loss or leakage of temporary restorative materials, by fracture of the tooth structure, and in teeth left open for drainage. Microorganisms can also penetrate the root canal system after root canal filling by loss or leakage of temporary or permanent restorative material, fracture of the tooth structure, recurrent decay that exposing the root canal filling material, or delay in placement of permanent restorations.

Persistent intraradicular infection

Microorganisms that can resist intracanal antimicrobial procedures and endure period of nutrient deprivation in prepared canal cause persistent intraradicular infection, this is also termed recurrent infection. Involved microorganisms are remnants of a primary or secondary infection. The microbiota associated with persistent infections is usually composed of fewer species than primary infections, and gram-positive facultative or anaerobic bacteria are predominant. Fungi can also be found in frequencies significantly higher when compare with primary infections.

Extraradicular infection

Extraradicular infection is characterized by microbial invasion of and proliferation in the inflamed periradicular tissues and is almost invariably a sequel to intraradicular infection. Extraradicular infection can be dependent on or independent of the intraradicular infection. The most common form of extraradicular infection dependent on the intraradicular infection is the acute apical abscess. The most common form of extraradicular infection that can be independent of the intraradicular infection is apical actinomycosis.

The Endodontic Microbiota

Molecular technology has enabled the recognition of new putative pathogens that had never been previously found in endodontic infections. Moreover, many species that had already been considered as putative pathogens because of their frequencies as reported by culture-dependent methods have been found in similar or even in higher prevalence values by molecular approaches, strengthening their association with causation of apical periodontitis. As a consequence, the endodontic microbiota has been clearly redefined by molecular biology methods.

Primary intraradicular infections

Sophisticated culture and molecular biology techniques have revealed the polymicrobial nature of endodontic infections, with a dominance of obligate anaerobic bacteria in primary infections. Current evidence reveals that endodontic bacteria fall into 8 of the 13 phyla that have oral representatives.

Gram-negative Bacteria

Gram-negative bacteria appear to be the most common microorganisms in primary endodontic infections. Species belonging to several genera of gram-negative bacteria have been consistently found in primary infections associated with different forms of apical periodontitis, including abscesses. These genera include Dialister (e.g., D. invisus and D. pneumosintes), Treponema (e.g., T. denticola and T. socranskii), Fusobacterium (e.g., F. nucleatum), Porphyromonas (e.g., P. endodontalis and P. gingivalis), Prevotella (e.g., P. intermedia, P. nigrescens and P. tannerae), and Tannerella (e.g., T. forsethia).

Gram-positive Bacteria

Even though anaerobic gram-negative bacteria are reported to be the most common microorganisms in primary infections, several gram-positive bacteria have also been frequently in endodontic mixed consortium, some of them in prevalence values as high as the most commonly found gram-negative species. The genera of gram-positive bacteria often found in primary infections include Pseudoramibacter (e.g., P. alactolyticus), Filifactor (e.g., F. alocis), Micromonas (e.g., M. micros), Peptostreptococcus (e.g., P. anaerobius), Streptococcus (e.g., S. anginosus group), Actinomyces (e.g., A israelii), Olsenella (e.g., O. uli), and propionibacterium (e.g., P. propionicum and P. acnes).

Persistent / Secondary Endodontic Infections

Most root canal-treated teeth with persistent apical periodontitis lesion have been demonstrated to harbor an intraradicular infection. Microorganisms present in root canal-treated teeth can be “persisters” that survived the effects of intracanal disinfection procedures and were present in the canal at the root canal filling stage (persistent intraradicular infection) or they can have infected the canal after filling as a result of coronal leakage (secondary intraradicular infection).

Available Nutrients

In the root canal system, Bacteria can utilize the following as a sources of nutrients: (1) the necrotic pulp tissue, (2) proteins and glycoproteins from tissue fluids and exudates that seep into the root canal system via apical and lateral foramens, (3) component of saliva that may coronally penetrate in the root canal, and (4) products of the metabolism of other Bacteria.

Microbiology of Periodontal Disease

Periodontal diseases can be defined as disorders of supporting structures of the teeth, including the gingivae, periodontal ligament and supporting alveolar bone. Periodontal diseases lead to damage of the periodontal tissues supporting the teeth (bone and connective tissue) and affect the quality of life of the affected individuals: poor alimentation, tooth loss, social and financial problems.

Periodontal disease can be broadly categorized into:

1. Gingivitis: the earliest stage of periodontal disease, infection affects only the gums.
2. Periodontitis is the more sever forms of the disease, when all of the supporting tissue are involved. Periodontitis, is infectious disease, can be classified into two main groups: chronic and aggressive. The chronic form is by far the most prevalent disease globally.

The initiation and progression of the inflammatory and destructive periodontal lesion is related not only to the presence of bacterial strains pathogenic for the periodontium, but also to the lack or minimal proportions of the beneficial microorganisms in a susceptible host . the relationship between periodontal microbiota and the host is generally benign but, when the specific bacterial species overgrows in the subgingival spaces, this may cause periodontal inflammation and destruction with attachment loss and bone loss.

Most of the periodontal pathogens are anaerobes but the biofilm can also harbour facultative aerobes, capnophiles and microaerophiles whose number depends on the environment in the developed biofilm and periodontal pocket. Most periodontal pathogens represent the true periodontal infection. Some bacterial species in the periodontal environment that are part of the commensal flora (*Actinomyces*, certain *Streptococcus* and *Staphylococcus* spp.) can provoke opportunistic infections in case of ecosystem disturbance.

Microbiota in different periodontal diseases

Many different bacterial species live in the healthy gingival sulcus and are present in different periodontal diseases. the bacterial flora associated with healthy periodontal tissue contains mainly Gram-positive microorganisms with a dominance of *Actinomyces* and *Streptococcus* spp. Gram- negative species and spirochetes may be also present in healthy patients, although in low concentration.

There is enough evidence to relate a small group of periodontopathogens with periodontitis and these bacteria have been defined as **key periopathogens**: *Actinobacillus actinomycetemcomitans*, *Tannerella forsythia* and *Porphyromonas gingivalis.*

three groups of factors that determine whether active periodontitis will occur in a patient:

1) a susceptible host,

2) presence of pathogenic species,

3) absence or a small proportion of “beneficial” species.

There is epidemiological evidence that **plaque-induced gingivitis** is a more prevalent periodontal disease, is more commonly generalized, and is more severe in individuals with poor oral hygiene. Development of this plaque-associated gingival lesion has been largely investigated in a model system of experimental gingivitis and it has been found that inflammatory features are related to emergence and growth of Gram-negative rods and filaments in the dental biofilm, and subsequently, of spirochetes and motile microorganisms.

1- *Actinobacillus actinomycetemcomitans*

A Gram-negative facultative non motile coccoid bacillus (oval to rod-shaped bacteria), non-spore- forming occurring as parasites or pathogens. its presence in the periodontal pocket associated with preadolescent, localized juvenile and advanced adult aggressive periodontal disease. Has several virulence factors such as; leukotoxin , cytolethal distending toxin , immunosuppression factors etc..

2- *Tannerella forsythia*

Gram-negative, anaerobic, fusiform bacterium and is an etiological agent in periodontal disease.

Is a non pigmented saccharolytic anaerobic Gram-negative rod , posses several virulence factors including the production of a trypsin-like protease and lipopolysaccharide and its ability to penetrate into host cells or induce apoptosis.

3- *Porphyromonas gingivalis.*

This bacterium is anaerobic , Gram negative rod , it is a black pigmented microorganism , has a carbohydrate capsule on its outer surface which inhibit phagocytosis by neutrophils and has protease (as a virulence factor) , which can effect the periodontium and cause damage to bone and gingiva . It is found in the oral cavity, where it is implicated in periodontal disease, as well as in the upper gastrointestinal tract, the respiratory tract and the colon.

Symptoms :

- This disease may progress slowly and at times, even painlessly. Some people do not notice that they have gum disease until it has progressed to periodontitis. The symptoms can be through the gum line or localized in one area. Symptoms could be;
- Bleeding Gums (after brushing or flossing)
- Chronic Bad breath (halitosis)
- Swollen Gums
- Gum inflammation (red gums)
- Receding Gums

- Periodontal pockets
- Uneven dentures or teeth bite.
- Loose teeth

Pathogenesis:

- The gingival tissues respond within 2 to 4 days to a beginning accumulation of microbial plaque with acute exudative vasculitis which termed the initial lesion.
- This response, which includes loss of perivascular collagen, is comparable to that elicited in most other tissues subjected to acute injury and may be a consequence of the elaboration and release of chemotactic and antigenic substances by microbial plaque. Within 4 to 10 days, the early lesion develops.
- It is characterized by a dense infiltrate of lymphocytes and other mononuclear cells, pathologic alteration of fibroblasts, and continuing loss of the connective tissue substance.
- The early lesion is followed by the established lesion which develops within 2 to 3 weeks and is distinguished by a predominance of plasma cells in the absence of significant bone loss
- . The established lesion, which is extremely widespread in humans, may remain stable for years or decades, or it may become converted into a progressive destructive lesion.
- . In the advanced lesion, plasma cells continue to predominate although loss of the alveolar bone and periodontal ligament.

Mode of transmission

- periodontal disease, may be passed from parents to children and between intimate partners. bacteria present on the oral soft tissues, teeth, tongue and saliva.

The oral defence mechanisms :

1. Non Specific Immune Defence; Saliva has many antimicrobial properties including:

    1. Antagonism between different microorganisms which produce inhibitory substances as bacteriocin produce by some streptococci.
    2. Lysozymes, they are derived from salivary glands and leukocytes they lyse the cell wall of gram positive bacteria these lysozyme present in blood, saliva ,tears and nasal mucosa .
    3. Peroxidase system, thiocyanate, hydrogen peroxidase may inhibit the growth of some oral flora.
    4. The mucosal barrier
    5. Salivary flaw, which is mechanical washing of oral bacteria
    6. Complement component and phagocytic transport by gingival crevicular fluid.

    7. Lactoferrin and transferring, this protein bind to iron which is essential nutrient for pathogenic bacterial multiplication (bacteriostatic).
    8. Natural salivary immunoglobulin (IgA) they affect the local host resistance to oral disease. Saliva IgA is the predominant Ig in saliva ,it prevents bacterial adherence and enhances their agglutination ,neutralize viruses ,however some bacteria produce

proteases which breaks sIgA such as Neisseria meningitis ,*Streptococcus pneumonia* and Gram negative bacteria .

2. Specific Immune Defences

The oral cavity has many lymphoid tissue as tonsil, soft palate, pharynx, tongue, salivary lymphoid tissue, scattered sub mucosal lymphoid tissue and gingival lymphocytes. The secretory IgA response against dental plaque antigen may be induced by two mechanisms.

1. Induction of local SIgA response resulted from stimulation of in lymphoid tissue of salivary glands .
2. Induction of generalized secretory IgA response via stimulation of gut associated lymphoid tissue GALT.

Prevention: The following steps can help reduce risk of developing periodontal disease:

- Stop smoking.
- Eat nutritiously.
- Follow good dental self-care practices.
- Get regular professional dental care.

Vaccine

Oral immunization focused on the development of a vaccine that could induce the production of Immunoglobulin A IgA (mainly salivary and other secretion with poor serum level) effective in production against caries.

Fungal cells

- **Fungal cells are of two basic morphological types:** true hyphae (multicellular filamentous fungi) or the yeasts (unicellular fungi), which make pseudohyphae. A fungal cell has a true nucleus, internal cell structures, and a cell wall. The main types of 'cells' produced by human pathogenic fungi are hyphae, yeast cells, and spores.
- Furthermore, hyphae may have some specialized structure or appearance that aids in identification.

Morphological types of fungi :

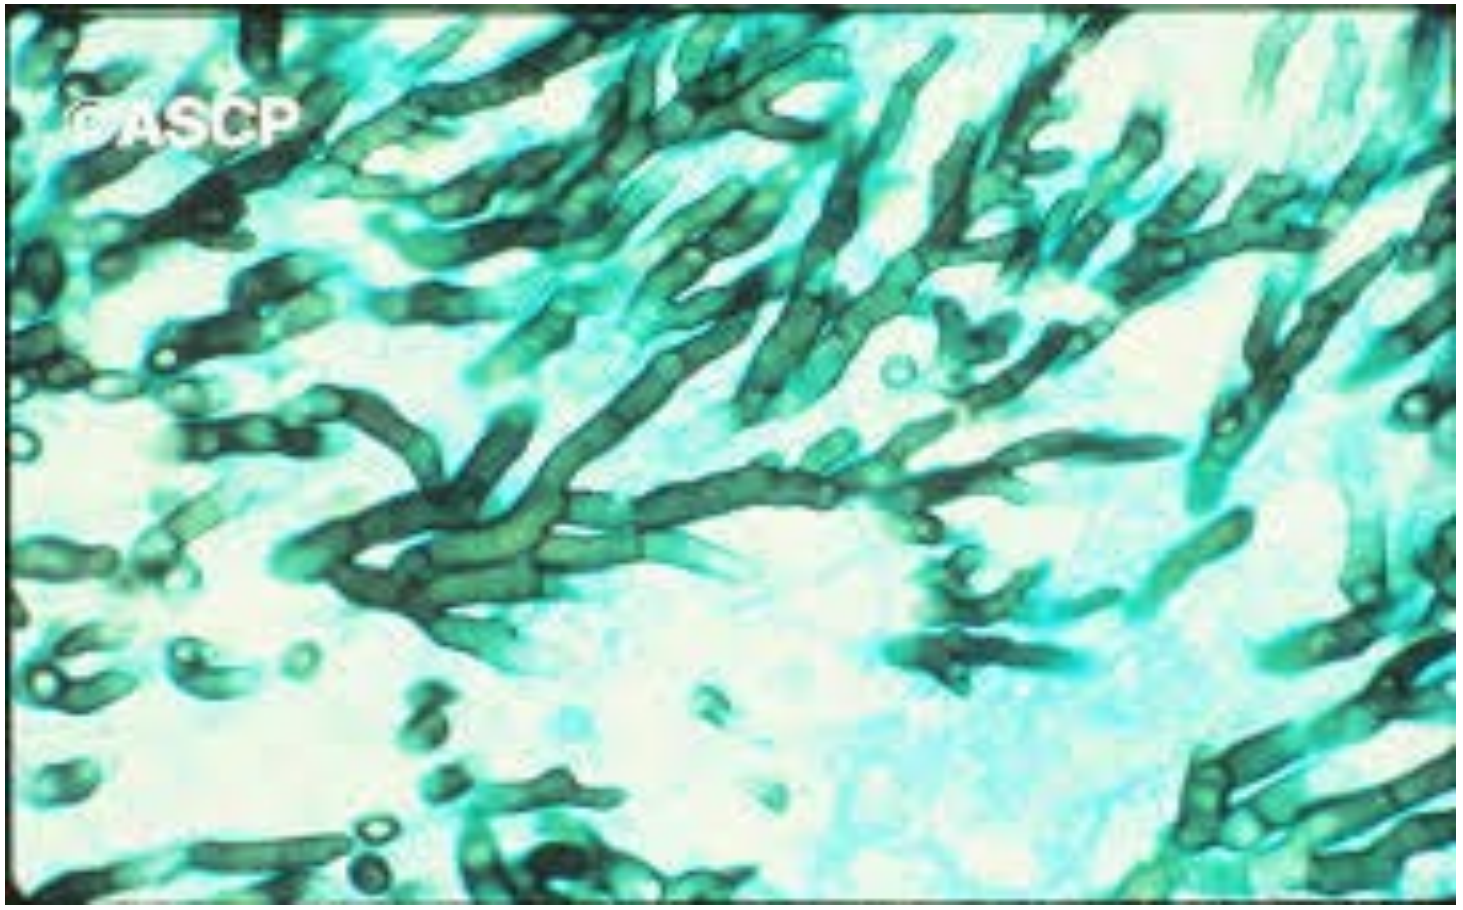
Three major groups :

1. Molds(filamentous)fungi.

2. Yeasts fungi.

3. Dimorphic fungi : fungi that have both a yeast stage and a mold stage , Mushrooms.

Filamentous fungi

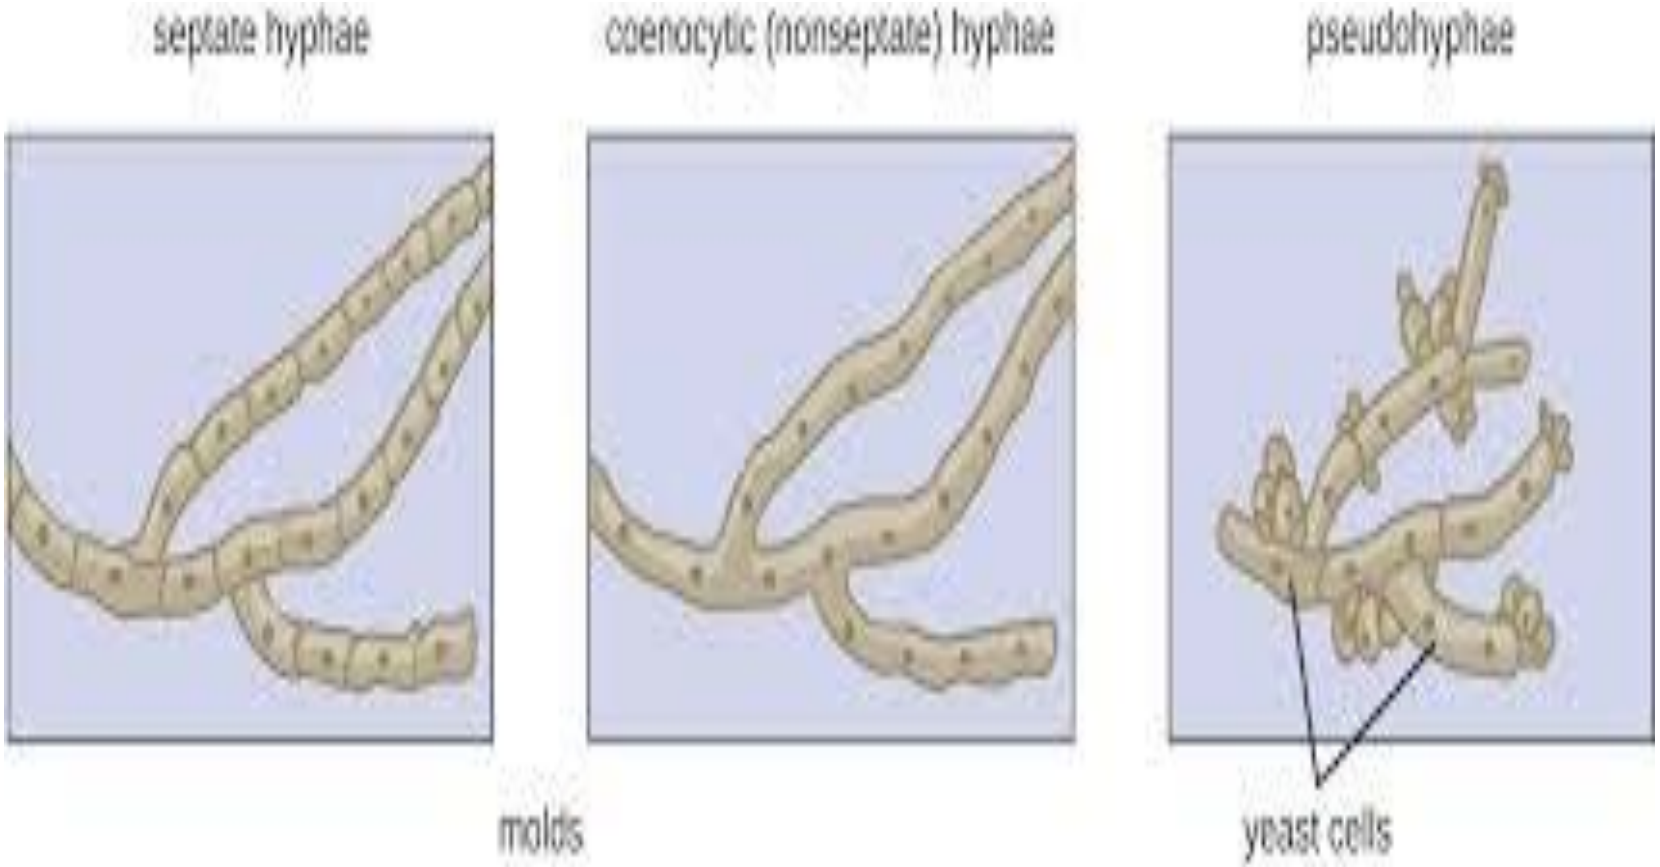


Fungi Groups

On the basis of Morphology

1. Molds (filamentous fungi)

- Most fungi are composed of filamentous (tubular) structures called hyphae. May be septated OR Aseptated



septate hyphae
coenocytic (nonseptate) hyphae
pseudohyphae
molds
yeast cells

Reproduction

- The simplest method of reproduction of fungi is by fragmentation of the thallus, the body of a fungus. Some yeasts, which are single-celled fungi, reproduce by simple cell division, or fission, in which one cell undergoes nuclear division and splits into two daughter cells; after some growth, these cells divide, and eventually a population of cells forms. In filamentous fungi the mycelium may fragment into a number of segments, each of which is capable of growing into a new individual.

Budding, which is another method of asexual reproduction, occurs in most yeasts and in some filamentous fungi. In this process, a bud develops on the surface of either the yeast cell or the hypha, with the cytoplasm of the bud being continuous with that of the parent cell. The nucleus of the parent cell then divides; one of the daughter nuclei migrates into the bud, and the other remains in the parent cell. The parent cell is capable of producing many buds over its surface by continuous synthesis of cytoplasm and repeated nuclear divisions.

- After a bud develops to a certain point and even before it is severed from the parent cell, it is itself capable of budding by the same process. In this way, a chain of cells may be produced. Eventually, the individual buds pinch off the parent cell and become individual yeast cells. Buds that are pinched off a hypha of a filamentous fungus behave as spores; that is, they germinate, each giving rise to a structure called a germ tube, which develops into a new hypha.

- Sexual reproduction, an important source of genetic variability, allows the fungus to adapt to new environments. The process of sexual reproduction among the fungi is in many ways unique. In fungi the nuclear membrane remains intact throughout the process, although gaps in its integrity are found in some species.
The nucleus of the fungus becomes pinched at its midpoint, and the diploid chromosomes are pulled apart by spindle fibres formed within the intact nucleus. The nucleolus is usually also retained and divided between the daughter cells, although it may be expelled from the nucleus, or it may be dispersed within the nucleus but detectable.

Hyphae: •

The majority of fungi are moulds, which are characterized by producing filamentous hyphae. Different types of hyphae possess unique combinations of structural, behavioural, and functional attributes.

•

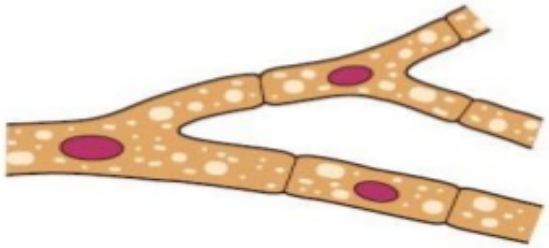
- The vegetative hypha at the periphery of a colony is a tip-growing cellular element that undergoes regular branching, is commonly multinucleate, and usually produces septa (cross walls). The mass of vegetative hyphae in the colony of a filamentous fungus is referred to as a mycelium. Many (but not all) filamentous fungi undergo prolific cell fusion within the colony to form a complex interconnected hyphal network.

Yeast cells •

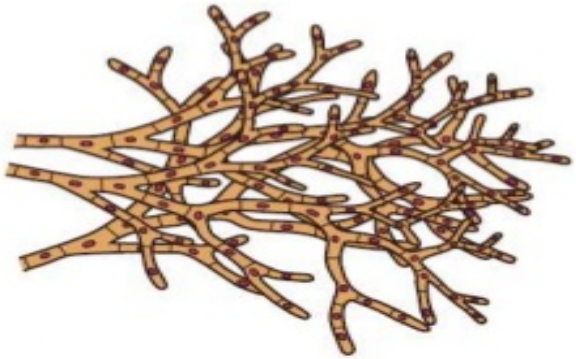
- Yeast cells are typically uninucleate single cells that reproduce vegetatively by processes involving septation and separation of daughter cells that can occur either by budding or by binary fission. The budding yeast *Saccharomyces cerevisiae* and the fission yeast, *Schizosaccharomyces pombe,* have been studied extensively as eukaryotic models, particularly in relation to the cell cycle and cell polarization.

Yeasts

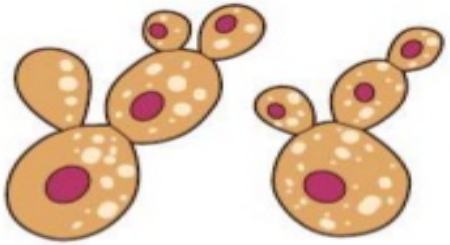
There are two basic morphological forms: **hypha** & **yeast**



a Hypha, septate, or nonseptate



b Mycelium: web of branched hyphae



c Yeast form, budding

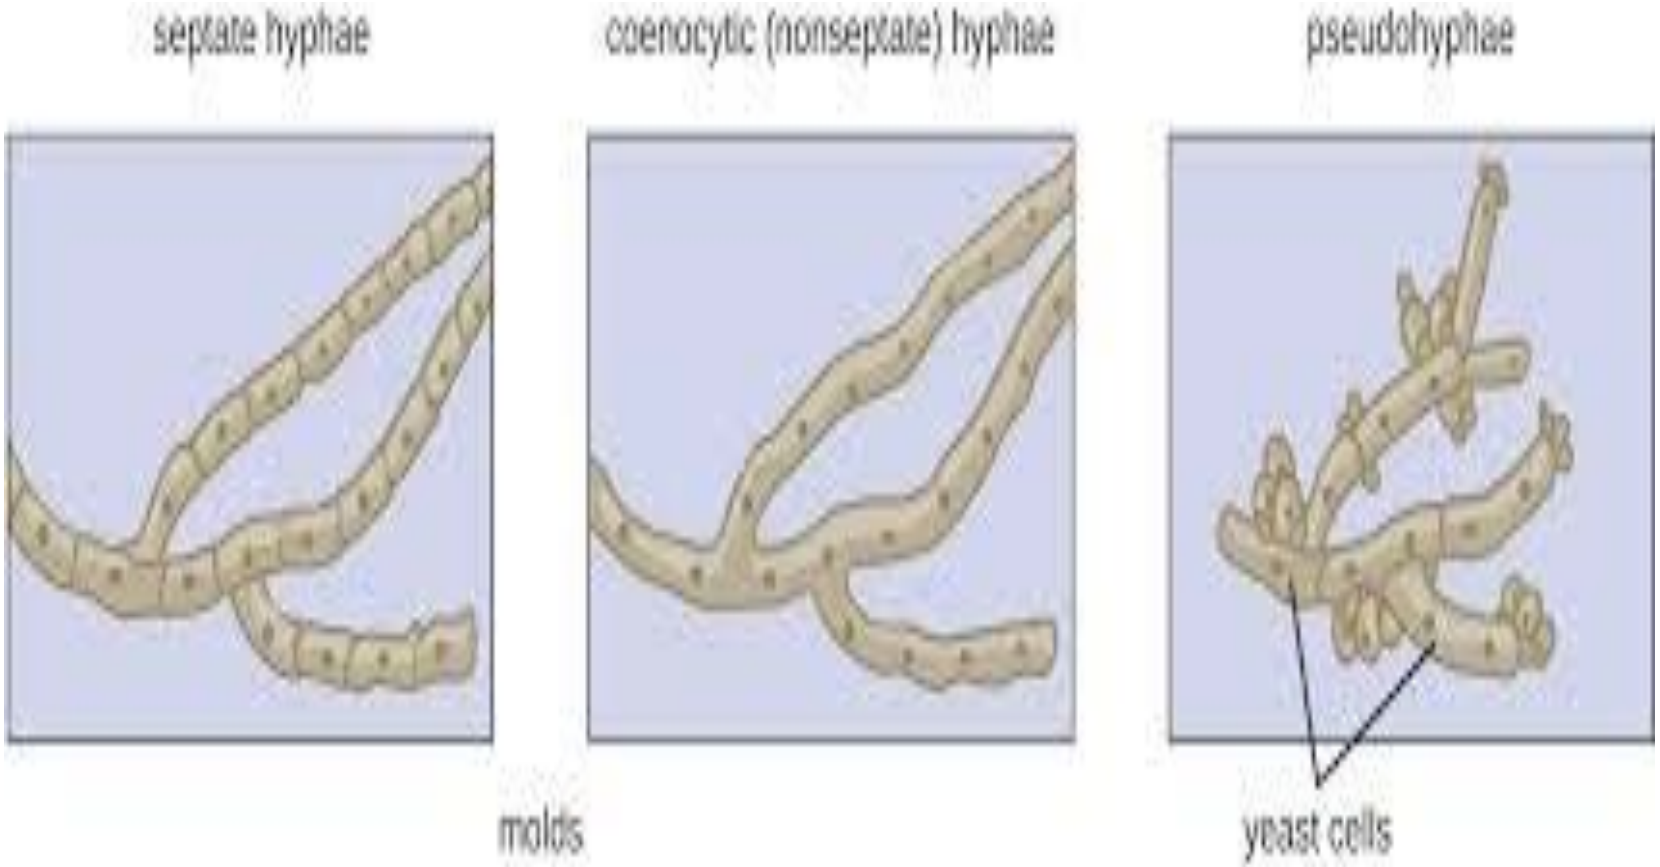
d Pseudomycelium

Basic Morphological Elements of Fungi

- Many important fungal pathogens produce yeast cells, and most of these (e.g. *Candida, Cryptococcus, Histoplasma, Blastomyces*, and *Paracoccidioides*) propagate themselves during infection by budding with the notable exception of the yeast cells of *Penicillium* (*Talaromyces) marneffei*, which reproduce by binary fission. Besides producing yeast cells, most of these pathogens are described as *dimorphic* or filamentous yeasts because, under certain conditions, they can produce hyphae . Indeed, some species (notably *C. albicans*) are often called *polymorphic* because they also form *pseudohyphae*, which more closely resemble yeast cells than hyphae.

Pseudohyphae •

These are formed by budding yeast cells • remaining attached and becoming elongated. Subsequent budding of these attached cells results in highly branched structures with constrictions between each cell. Mechanical agitation easily disrupts the attachment between pseudohyphal cells.



septate hyphae
coenocytic (nonseptate) hyphae
pseudohyphae
molds
yeast cells

Dimorphism •

The ability to exhibit dimorphic switching • between a yeast and a hyphal growth form is a key feature of many human fungal pathogens. In *C. albicans*, both morphological forms, as well as pseudohyphae, are important for virulence and have distinct functions during the different stages of disease development, including adhesion, invasion, damage, dissemination, immune evasion, and the host response.

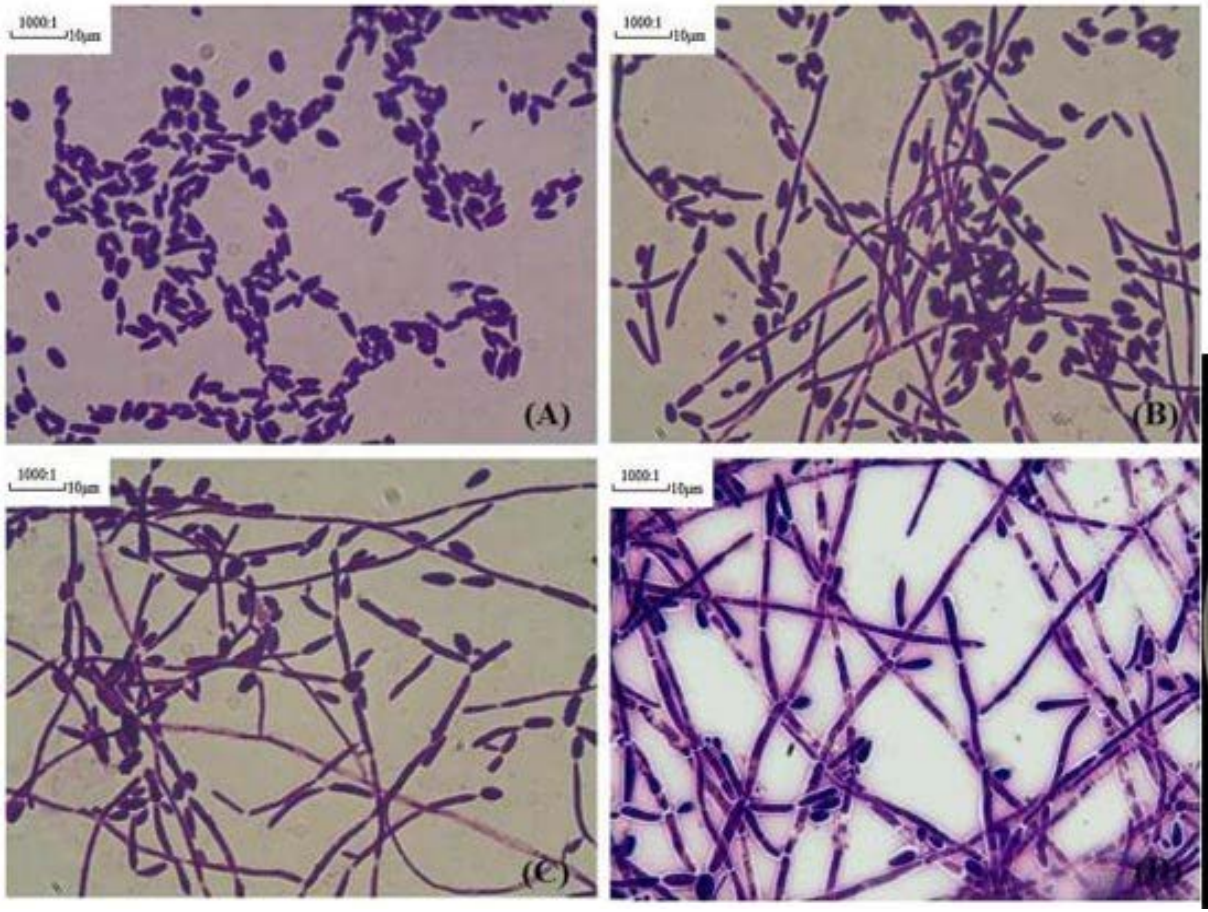
Oral Aspect of fungal infections

Fungal infections in the oral and perioral regions occur either as primary localized lesions or as manifestations of systemic mycoses. The most common group of fungal infections that dental practitioners diagnose and treat are caused by Candida spp. Some of the rarer mycoses such as histoplasmosis .

-

- The majority of opportunistic oral mucosal fungal infections are due to *Candida albicans* and *Aspergillus fumigatus* species. *Mucor* and *Cryptococcus* also have a major role in causing oral infections, whereas,*Fusarium*,*Saccharomyces* and *Penicillium marneffei* are uncommon pathogens in the oral cavity. The broad spectrum of clinical presentation includes pseudo-membranes, abscesses, ulcers, pustules and extensive tissue necrosis involving bone.

- Yeasts occur commonly in the oral cavity in healthy individuals. The prevalent species is Candida albicans (about 60-70% of all isolates) and C. tropicalis. The yeast flora increases in many patient groups, especially those who are immunocompromised.
- **C. albicans** is the most important species, being the cause of almost all cases of yeast infections in the region, often in association with other species. The number isolated from the oral cavity depends on testing site and methods used.



Candida tropicalis

- Other species responsible for oral infections have also been identified including C. glabrata, C. krusei, C. parapsilosis, and C. tropicalis.

Candidiasis

- Is a primary or secondary mycotic infection caused by members of the genus Candida , the clinical manifestations may be acute, sub- acute or chronic and involvement may be localized to the mouth, throat, skin, scalp, vagina, fingers, nails, bronchi, lungs, or the gastrointestinal tract, or become systemic as in septicemia, endocarditic and meningitis .Systemic candidiasis is usually seen in patients with cell-mediated immune deficiency, and those receiving aggressive cancer treatment, immunosuppression, or transplantation therapy.

Oral candidiasis

Thrush •

It is an infection of mouth caused by Candida and the common sign of thrush is the presence of creamy white , slightly raised lesion of the mouth . The lesion , may have a "cottage cheese " appearance , in severe cases , may spread into the esophagus, causing pain or difficulty swallowing .

Stomatitis

Stomatitis is an inflammation of the mucus lining of any of the structures in the mouth which may involve the gums , tongue , lips and throat .

Erythematous candidosis

- Related to dentures is the most common form of oral candidosis in about 50 % of denture wearer.

Oral thrush

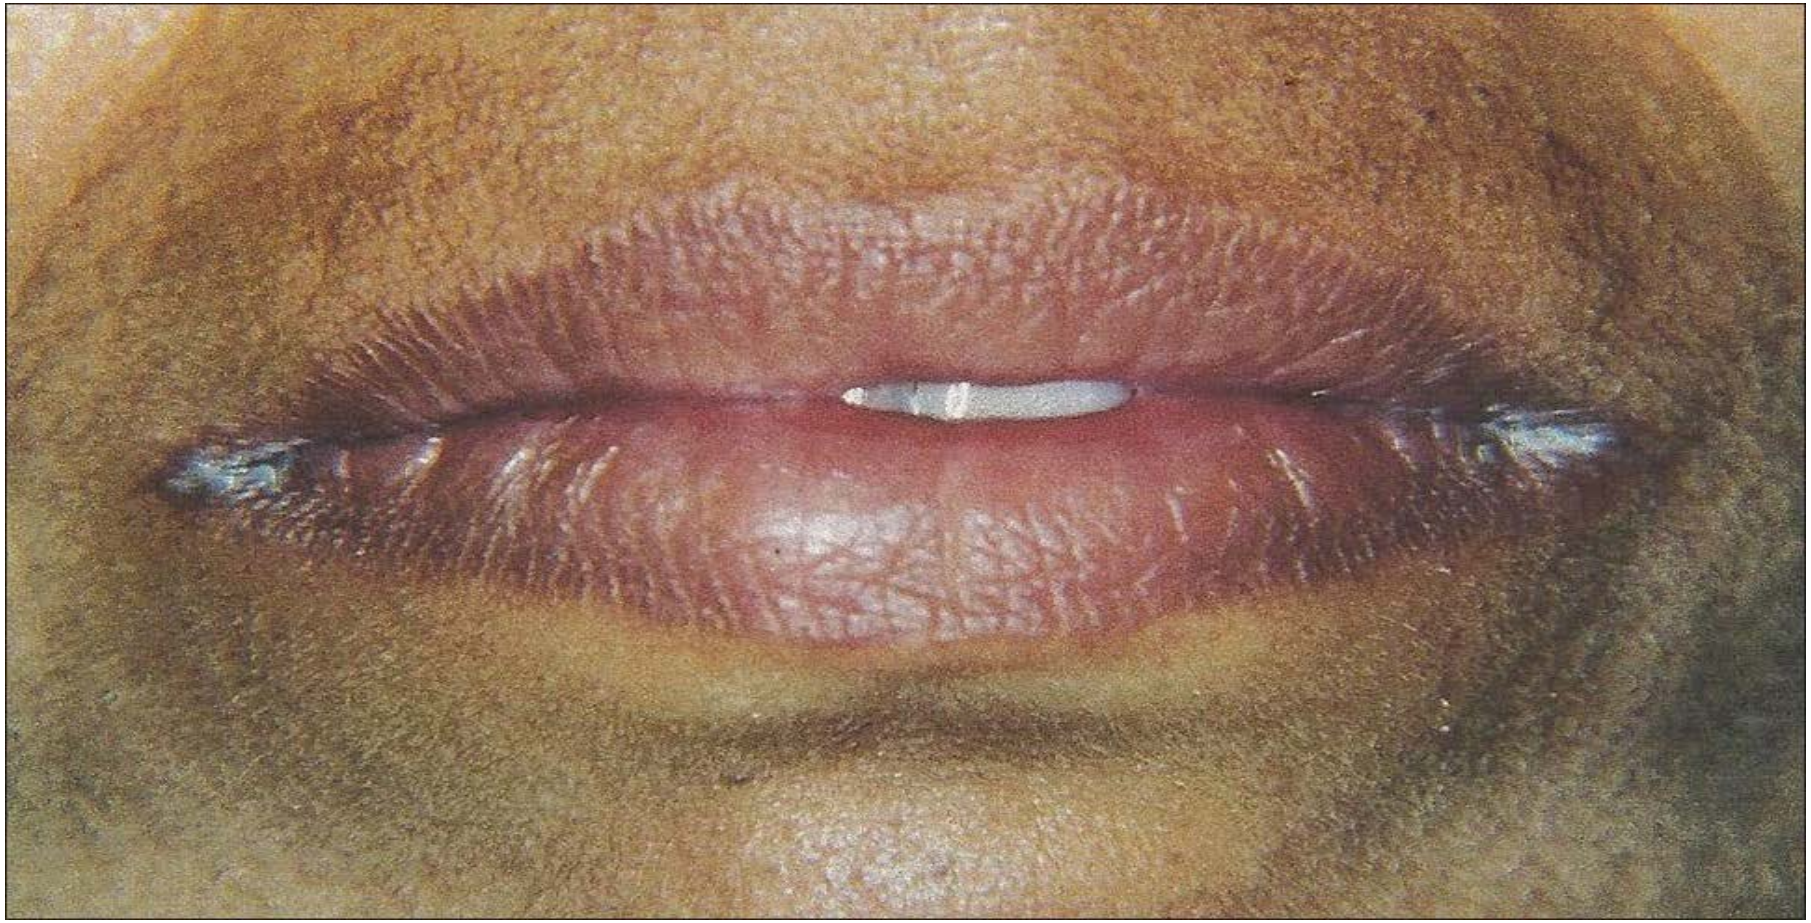
Candida-associated denture stomatitis

Candidiasis

Angualr cheilitis •

Angular cheilitis is an inflammatory lesion at the corner of the mouth and often occurs bilaterally. Nutritional deficiencies such as vitamin B12 and iron also some underlying causes for angular cheilitis . It also reported that angular cheilitis is one of the common presentations of oral candidiasis in HIV infected patients.

Angular cheilitis



Pathogenesis •

The ability of Candida to adhere to the mucosa and dentures plays an important role in the pathogenesis of oral yeast infections . Adherence is achieved by specific and nonspecific mechanisms. However the mechanisms of are still not fully understood . Local defense mechanisms have a key role in preventing yeast colonization in the oral cavity.

- These include the physical local barrier of the epithelia, secretory immunoglobulin A, and salivary factors such as flow rate and specific molecules (lysozyme, histatin and lactoferrin). Secreted aspartic proteinase (SAP), phospholipases and lipases are extracellular enzymes that facilitate adherence and/or tissue penetration. SAPs efficiently degrade extracellular matrix and host surface proteins (laminin, fibronectin, and mucin).

Histopathology •

The histological profile of C. albicans infections shows yeasts and pseudohyphae. C. glabrata, however, appears to produce only yeast forms . Histopathologic response is in most cases characterized as inflammatory or as an abscess.

Examples risk patients for oral candidiasis

- Patients with dental prosthese
- Patients with reduced salivary flow rate
- Patients with oral mucosal diseases
- Asthmatic patients on corticosteroid therapy
- Diabetic patients
- Patients with rheumatic diseases
- HIV infected and AIDS patients
- Patients with malignant disease
- Patients receiving immunosuppressive drugs
- Patients receiving radiotherapy to the head and neck
- The elderly.

Identification of Candida

- Microscopic examination of the smears stained KOH preparation can reveal candidal hyphae and blastospores.
- Culture on Sabouraud's dextrose agar (SDA) at 25-30^{o}C for 48-72 hours.Germ tube growth can be used for identification of *C. albicans*.

- CHROM agar is a medium that is widely used to identify C. albicans, C. krusei, and C..tropicalis. The medium contains chromogenic substrates which react with enzymes secreted by the target micro-organisms to yeald colonies of varying colours. C.albicans forms green colonies, C.tropicalis steel blue colonies, and C.krusei forms rose coloured colonies.

Aspergillosis

- Aspergillosis has been reported as the second most prevalent opportunistic fungal infection. *Aspergillus* species are universally found in humid areas, damp soil, grain, cereal, mouldy flour and organic decaying or decomposing matter. In the hospital setting, construction activities, rotten leaves or insufficient cleaning of dust can increase the risk of developing aspergillosis. *Aspergillus fumigatus* is the most familiar pathogen of the species. Human infections are also caused by less common *Aspergillus* species, such as *Aspergillus flavus*, *Aspergillus terrus*. The most common species encountered is A. flavus followed by *Aspergillus fumigatus* and *A. niger*.

Aspergillosis ulcer

Clinical presentation

- Aspergillosis generally occurs after inhalation of spores, that can result in both upper and lower respiratory tract infection- bronchopulmonary aspergillosis. From lungs, infections may spread to the brain, bone or endocardium. Paranasal sinuses, larynx, eyes, ears and the oral cavity may be involved in primary aspergillosis. *A. fumigatus* is the usual agent of sinus aspergillosis, whereas *A. flavus* is more common in invasive lesions in immunosuppressed individuals. Orofacial aspergillosis is relatively common in patients undergoing treatment for malignancies of the blood and blood-forming organs.

CRYPTOCOCCOSIS

- Cryptococcus is another very important human fungal pathogen that grows inside the host as budding yeast cells. The main characteristic feature of yeast cells of *Cryptococcus* is the formation of a polysaccharide capsule around a melanized cell wall. The capsule grows in size within the host and is considered to be the main virulence factor of *C. neoformans* because it has multiple effects on the host, including inhibiting phagocytosis by macrophages and modulating the host's innate and adaptive immune responses.

- *Cryptococcus neoformans* and *Cryptococcus gattii* are commonly considered as the causative agents of cryptococcosis. *C. neoformans* generally affects immunocompromised hosts whereas *C. gattii* is isolated more from immunocompetent individuals.

Clinical presentation

- *C. neoformans* infections usually occurs after inhalation of fungal spores from the soil and excreta of birds. In immunocompetent individuals the infection remains subclinical within the lungs. In the immunocompromised host, the fungus produces rapid disseminated infection involving central nervous system, skin, mucous membranes and many other tissues.

Diagnosis

- Histopathology varies according to the immunological status of the host. In immunocompetent hosts, typical granulomas are formed at the site of cryptococcal infection, with multinucleated giant cells containing intracytoplasmic cryptococci in budding forms. In immunosuppressed patients, proliferating cryptococci present as extra- and intracellular yeast cells with some budding forms with reactive macrophages, minor lymphocytic and neutrophilic infiltrate. The definitive diagnosis of cryptococcosis is established with periodic acid Schiff (PAS), and mucicarmine-stained preparations. The fungal cytoplasm appears bright by PAS stain and mucicarmine stains the fungal capsule. Culture and assay of serum or cerebrospinal fluid for capsular antigen is useful.

Histoplasmosis

- Histoplasmosis is caused by *Histoplasma capsulatum*. The disease can affect the lungs and cause acute or chronic respiratory problems in the immunocompromised population.. The reticuloendothelial system, gastrointestinal tract and kidneys are also affected by this fungus. Histoplasmosis may sometimes appear in a mucocutaneous form that can manifest as ulcerating or nodular lesions in the oral mucous membrane. The oral lesions may also appear granulomatous and may be painful, localized on the oral mucosa, tongue or lips. The ulcers may often resemble carcinoma or tuberculosis because of the raised and rolled borders, usually covered by a yellow or greyish membrane.

Diagnosis

- Diagnosis is usually confirmed by microscopy, culture and serology. The serum immunodiffusion assay that detects antibodies against the H and M antigens of *H. capsulatum* is reported to be a reliable diagnostic method.

Histoplasmosis ulcer

Blastomycosis

- Blastomycosis is a rare fungal disease caused by *Blastomyces dermatitidis*, a spore found in the soil, when inhaled, it can cause disseminated disease or a localized respiratory condition. When the disease affects the oral cavity, it produces ulcerating mucosal lesions as well as sessile projections, granulomatous or verrucous lesions. Small ulcers are characteristic oral manifestation and may present as a primary lesion or secondary to disseminated disease. The isolation of the fungus from clinical specimens and histopathological examination of appropriately stained sections are the definite method for establishing diagnosis. The fungus grows well in standard mycological media such as sabouraud dextrose agar SDA, potato dextrose agar or inhibitory mold agar. Classically appears as round to oval, multinucleate yeast cell with a single broad-based bud under the microscope.

SACCHAROMYCES INFECTION

- *Saccharomyces cerevisiae* (also known as “baker's yeast”) is widespread in nature and is a commensal inhabiting the gastrointestinal tract of humans. *S. cerevisiae* is now included in some diet or health foods. Fungemia from *S. cerevisiae* can follow the use of live yeast capsules of *Saccharomyces boulardii* which are used as probiotics for the prevention and treatment of various diarrheal disorders.

Clinical presentation

- Lesions resemble invasive candidiasis due to the presence of esophagitis in both conditions. Fever may be present in majority of patients. Deep site involvement with necrosis and granulomatous reaction has also been reported. Intra-oral manifestations include ulcers with associated painful swallowing, dry mouth and burning sensation.

Diagnosis

- Direct Gram stain from the swab will show majority of Gram-positive budding yeast cells. The culture will give creamy-white yeast-like growth. The Gram staining from the colony will show budding yeast cells without any capsule. The organism can be identified using corn meal agar and carbohydrate assimilation test.

Thank you •

Oral fungal infections (Mycosis)

Oral candidosis

Candida species are fungi that are frequently encountered in the mouth of healthy individuals and as such can be considered to be normal residents of the oral microflora. The actual incidence of oral candida carriage is estimated to be between 35 and 55% of healthy individuals,. Other fungi, such as *Saccharomyces* pp., *Geotrichum* spp. and *Cryptococcus* spp. are also encountered (Table 1), but their occurrences are rare and these are not generally implicated with oral infection. While *Candida* species are normally harmless commensals, when conditions in the mouth alter to one that favours proliferation of *Candida*, a shift to a pathogenic state can occur. As such, *Candida* infection is invariably an opportunistic one dependent upon some form of underlying host predisposition. Infection with *Candida* is described as a candidiasis. •Fungal infections are classified as superficial, opportunistic or systemic.

Classification

There are three groups of interest to dentists:

1-Dermatophytes cause superficial skin infections e.g. ring worm and athletes foot.

2- Opportunistic fungi, which are present in the environment or in the human normal microflora, cause disease especially in the compromised host, e.g. Candia spp. and Aspergillus spp.

3-Systemic pathogens, which are the most virulent, can cause systemic disease in previously healthy individuals e.g. Blastomyces spp. and Cryptococcus spp.

Pathogenic *Candida* species: The genus *Candida* contains over 200 different species that are ubiquitously distributed. However, only a few of these have been implicated in human infection. The most prevalent *Candida* species recovered from the human mouth, in both commensal state and cases of oral candidiasis, is *Candida albicans*. It is estimated that this species accounts for over 80% of all oral yeast isolates. In terms of oral prevalence, *C. albicans* is followed by *C. glabrata, C. krusei, C. tropicalis, C. guilliermondii C. kefyr and C. parapsilosis*

Table 1-Fungal species recovered from the human mouth	
***Candida* species**	***Other fungal species(rare)***
Candida albicans	*Paracoccidioides brasiliensis*
Candida glabrata.	*Aspergillus* spp.
Candida tropicalis	*Cryptococcus neoformans*
Candida krusei	*Histoplasma capsulatum*
Candida lusitaniae	*Mucor* spp.
Candida dubliniensis	*Saccharomyces* spp.
Candida kefyr	*Geotrichum* spp.
Candida guilliermondii	*Rhizopus* spp.
Candida parapsilosis	

Candida virulence factors

The transition of *Candida* from a harmless commensal to a pathogenic organism is complex and may relate to subtle environmental changes that lead to the expression of a range of virulence factors .It is likely that it is the combined effect of both host and candidal factors that ultimately contribute to the development of oral candidiasis.

*Adherence

-One of the key virulence factors of *Candida* spp. is the ability to adhere to host surfaces. In the oral cavity, this allows the organism to avoid removal through the effects of salivary flow and swallowing.

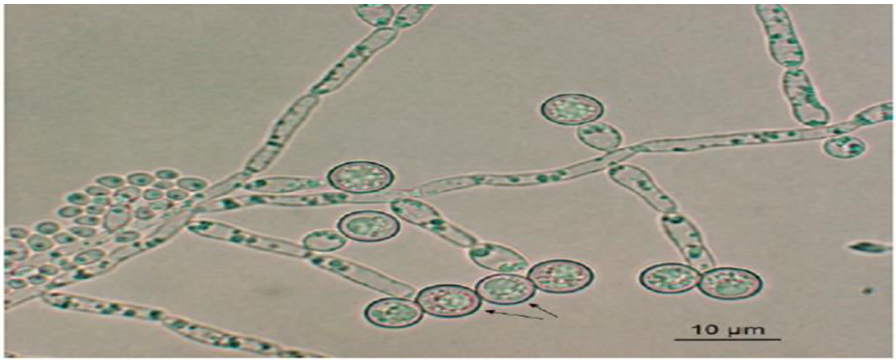
-Adherence can be to oral epithelial tissue or to biomaterials of prosthetic devices such as dentures.

-Attachment to such oral surfaces can be specific or non-specific The cell surface molecules on *Candida* that are involved in its specific adherence are described as adhesins . Adhesins include receptors and proteins that bind to complement receptors on host cells.

Morphology

Candida have the ability to grow in several morphological states including **budding yeast cells, pseudohyphae** (Fig.1b) (elongated chains of yeast cells), and also **true filamentous hyphae** (Fig. 1a). Once attached to host surfaces the ability of *Candida* and in particular *C. albicans* to **switch** from its yeast morphology to a filamentous form may promote penetration of the epithelium and increase resistance of cells to phagocytosis by host immune cells *C. albicans* show filamentous strains are virulent.

Fig .1a



Phenotypic switching :<u>**Switching**</u> has multiple effects on the *Candida* cells and is associated with altered gene expression which affects* surface antigenicity, *adhesiveness, *drug susceptibility, and *resistance to phagocytosis . A high switching mode is a strain-dependent trait and can clearly influence strain virulence.

Fig.1b

*Hydrolytic enzymes

_Secreted a spartyl proteinases (SAPs) :) Have the ability to degrade host extracellular matrix proteins would be an obvious pathogenic factor as would the destruction of host proteins involved in defense against infection.

_Phospholipases (PLs) :PLs factors in *Candida* pathogenicity. Phospholipases are enzymes that hydrolyse phospholipids into fatty acids, their production could contribute to host cell membrane damage which could promote cell lysis or expose receptors to facilitate adherence.

Oral candidiasis: The oral candidiasis high incidence in Human Immunodeficiency Virus (HIV)-positive individuals and Acquired Immunodeficiency Syndrome(AIDS) sufferers. However, transition from healthy oral carriage to a diseased state can be triggered by less extreme changes within the oral environment and numerous other factors have been implicated (Table 3).

Table 3- Host related factors associated with oral candidiasis.
Suggested host factor
Local host factors
• Denture wearing • Steroid inhaler use • Reduced salivary flow • Carbohydrate rich diet

Systemic host factors
• Extremes of age • Endocrine disorders *e.g.* diabetes • Immunosuppression • Receipt of broad spectrum antibiotics • Nutritional deficiencies

A-Pseudomembranous candidiasis

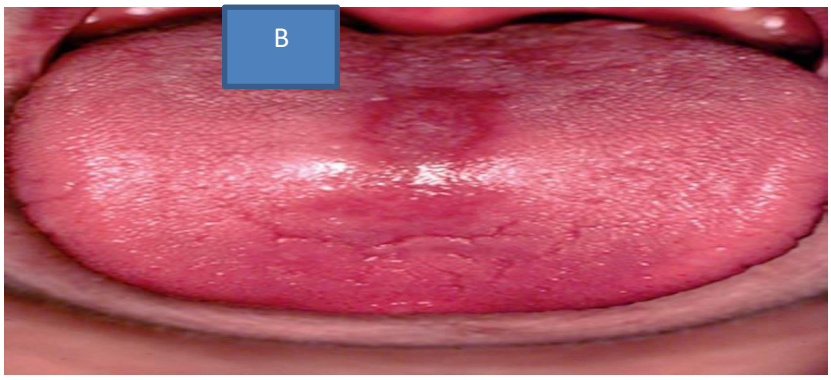
Acute pseudomembranous candidiasis is a classic form of oral candidiasis, commonly referred to as thrush, most common type of oral candidiasis, accounting for about 35% of oral candidiasis cases . (Fig..2A) is white plaque-like lesions on the oral mucosa and has been found in the mouths of neonates and in the elderly. Pseudomembranes occur on the surface of the labial and buccal mucosa, hard and soft palate, and tongue. The lesions can be removed by gentle scraping to reveal the underlying erythematous mucosa and this is a diagnostic clinical feature of the infection.

When viewed by light microscopy, the removed pseudomembranes are seen to consist of desquamated epithelial cells and fungal elements It is classically an acute condition, appearing in infants, people taking antibiotics or immunosuppressant medications, or immune-compromising diseases. It can be chronic and intermittent, even lasting for many years. Chronicity of this subtype generally occurs in immunocompromised states, (e.g., leukemia, HIV) or in persons who use corticosteroids topically or by aerosol.

B-Acute erythematous candidosis

Acute erythematous candidosis (Fig. 2B) is characterized by the presence of painful reddened patcheson the oral mucosa, typically on the dorsum of the tongue, associated with the administration of a broad spectrum antibiotic,particularly if the patient also uses a steroid inhaler. Antibiotic decreases the bacterial community within the oral microflora,allowing

Candida numbers to increase. Cessation of antibiotic treatment will generally result in resolution of the lesion. The relationship between antibiotic therapy and this form of oral candidosis has resulted in the use of an alternative description,namely, 'antibiotic sore mouth



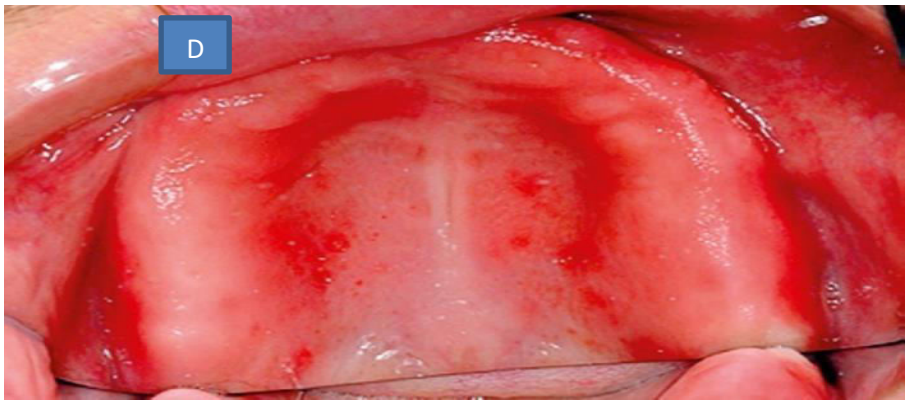
C-Chronic hyperplastic candidosis

Rare form of oral candidosis seen in middle aged men who are tobacco smokers. The condition is generally asymptomatic and if left untreated some cases(5–10%) go on to exhibit dysplasia and subsequent development of oral cancer at the lesional site. CHC is characterized by the invasion of the oral epithelium by hyphal forms of *Candida*. The condition can occur at any site on the oral mucosa but is most frequently encountered as bilateral white patches in the buccal commissure regions. The lesions cannot be removed by gentle scraping without bleeding and two lesional types have been described based on clinical appearance. **Homogeneous** lesions are smooth and white which contrasts with **heterogeneous** lesions where areas of erythema can be seen giving a nodular or speckled appearance to the infected site. The heterogeneous form of the lesion that is more prone to malignant transformation

D-Chronic erythematous candidosis

The most frequently encountered form of oral candidosisis chronic erythematous or '*Candida* associated denture stomatitis' (Fig..2D). This infection presents as reddening of the mucosa beneath the fitting surface of a denture. Upto 65% of denture wearers have clinical signs of this condition, This condition can develop under any acrylic denture or intra-oral appliance, but is

almost invariably seen in the palate rather than on the mandibular mucosa. In adequate oral hygiene or the presence of a poorly fitting denture are both strongly associated with chronic erythematous candidosis

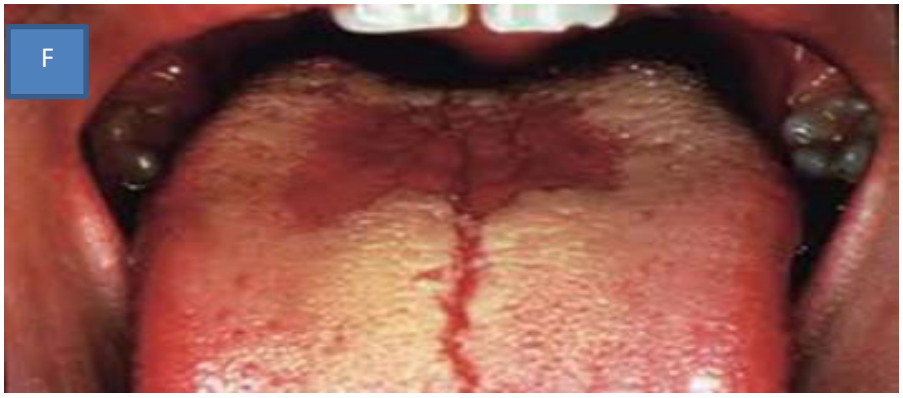


Other secondary forms of oral candidosis

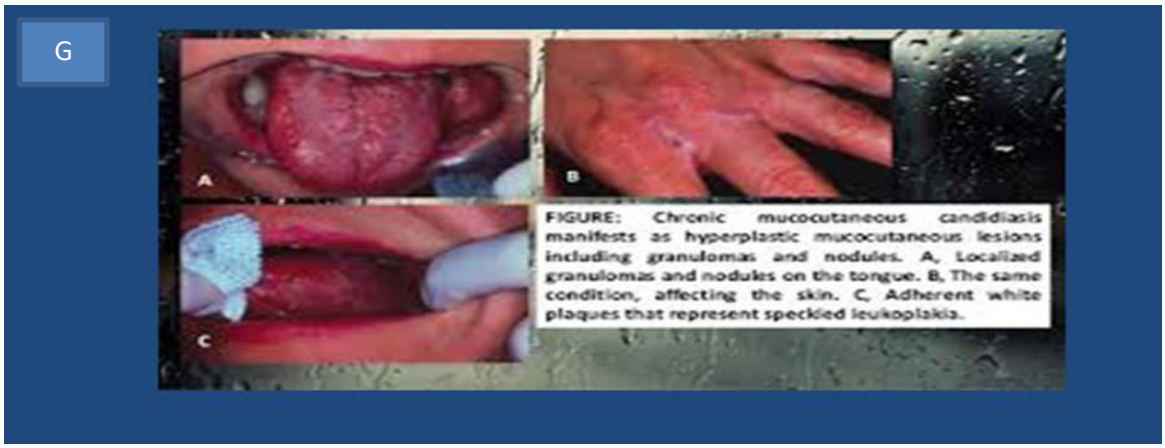
E-Angular cheilitis

Angular cheilitis characteristically presents as erythematous lesions at the corners of the mouth .The condition is associated with chronic erythematous candidosis. While *Candida* can be recovered from the lesional sites, the exact role of this organism in the infection can be difficult to as certain as frequently bacterial species such as *Staphylococcus aureus* or streptococci are also present.

F-Median rhomboid glossitis : As a symmetrical shaped area in the midline of the dorsum of the tongue. The condition is chronic and represents a trophy of the filiform papillae. Recovery of *Candida* from this area is high, and the condition would appear to be strongly associated with both smoking and the use of inhaled steroids.



G-Chronic mucocutaneous candidosis: This is a rare group of disorders characterized by persistent superficial candidal infection of the mouth, other mucosal surfaces, the skin and nails. The oral lesions resemble those of chronic hyper-plastic candidosis and can involve any part of the mucosa.



Host response to oral candidosis

Appropriate host immunity is essential in the preventionof oral candidosis **Innate immunity** is first encountered in the oral cavity in the form of **antimicrobial peptides** (AMPs), also referred to as ***host defence peptides found in saliva** or released by oral epithelial cells. Release of these molecules from epithelial cells is believed to be triggered when ***Candida* binds to a particular group of receptors on epithelial cell surfaces**. These receptors are often referred to as pattern-recognition receptors PRRs,and toll-like receptors (TLRs) are a major class of these. In humans, TLR2 and TLR4 are responsible for recognising fungal pathogens resulting in activation of intracellular pathways leading to cytokine production,activation of the innate immune response and release of AMPs.Examples of AMPs include lactoferrin, α- andβ-defensins, histatins, lysozyme, secretory immunoglobulin A, mucins, sialo peroxidase and transferrin. The main function of these molecules is to either kill the colonising *Candida* or limit its adherence to oral surfaces. Histatins have an anti-candidal activity**.**Also of importance in early host defence is the ***phagocytotic** clearing of *C. albicans* (PMNs) and monocytes.

. The phagocyte-dependent protection of the host can be promoted or impaired by the release of cytokines by T-helper (Th) cells. The type of Th response generated can be influenced by the effect of the infecting organism on antigen-presenting cells

(APCs)such as dentritic cells (DCs) .After contact with *Candida*, or its products, DCs migrate into the draining lymph node where they mature and directCD4+ T cells to develop into either Th1 or Th2 cells through *Candida* antigen presentation and cytokine production.The Th1 is associated with macrophage activation and enhanced resistance against reinfection,Th2 is linked to the development of chronic disease.

.***Serum antibodies** probably constitute a secondarydefence line and become important once either tissue penetration or systemic infection occurs.

Diagnosis of oral candidosis

Diagnosis of oral candidosis can often be made on the nature of the clinical presenting features although microbiological specimens should be taken if possible in order to both identify and quantify any *Candida* that may be present and provide isolates for antifungal sensitivity testing. Identification of infecting strains is important since the emergence of species with reduced sensitivity to frequently administered antifungals is becoming increasingly evident.

Isolation of *Candida* from the oralcavity

Oral samples can be obtained by a variety of methods(Table 9.4)

Table 9.4 Methods of recovering *Candida* from the oral cavity.

Isolation method	Advantages	Disadvantages
Culture of whole saliva	Sensitive; viable organisms isolated	Problems may occur with collection of sample; not site specific
Concentrated oral rinse	Quantitative; viable cells isolated	Some patients have difficulty in using rinse; not site specific
Swab	Simple to use; viable cells isolated; site specific	Difficult to standardise
Smear	Simple to use; not reliant on culture	Viable cells not determined; species identity not readily confirmed
Imprint culture	Quantitative; viable cells isolated; site specific	Some sites difficult to sample
Biopsy	Essential for chronic hyperplastic candidosis	Invasive; not appropriate for other forms of candidosis

Uncommon oral fungal infections

Aspergillosis

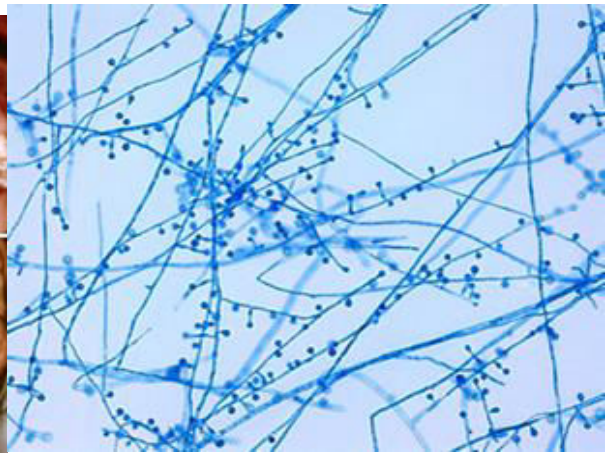
- Second commonest fungal infection in human
- Commonly seen with high dose of corticosteroid use, organ and marrow transplantation, increase use of immunosuppression against autoimmune diseases
- Lungs are commonly affected
- Also invade blood vessels causing thrombosis and infarctions
- Less commonly affect maxillary sinuses

Oral lesions are typically black or yellow necrotic soft tissues

Cryptococcosis

- Primarily affects lungs and can lead to meningitis
- Caused by *Cryptococcus neoformans*, usually isolated in pigeon's and other birds' droppings
- Cutaneous lesions : Face, neck and scalp
- Oral lesions are rare; resembles superficial ulcerations, granulomas, nodules or indurated ulceration similar to carcinoma

Blastomycosis:Caused by Blastomyces dermatitidisWhen inhaled, spores produce disseminated or local respiratory infections.Oral lesions are rare.May produce ulcerated mucosal lesions in the oral cavity.



Histoplasmosis

- Caused by *Histoplasma capsulatum*; a dimorphic fungi
- Two forms; pulmonary and mucocutaneous
- Mucocutaneous form cause ulcerative/erosive lesions on tongue, plate and buccal mucosa
- Oral lesions: single ulcers, long term and may or may not be painful
- Always misinterpreted as malignant ulcers
- Involvement of the oral cavity is secondary to paranasal sinuses or nasal cavity
- Usually present as a palatal necrosis or ulcerations
- Extends to adjacent structures causing extensive tissue necrosis and invasion of brain
- Organ transplant and poorly controlled diabetic patients are susceptible

Fusiform and Spirochaetes

Zainab kamil yousif

Medical microbiology

Third year

Fusobacterium

- *Fusobacterium* is a genus of anaerobic, Gram-negative, non-sporeforming bacteria, similar to *Bacteroides*. Individual cells are slender, rod-shaped bacilli with pointed ends.[2][3] Strains of *Fusobacterium* cause several human diseases, including periodontal diseases and topical skin ulcers.

Fusobacterium

- *Fusobacterium* spp. can be somewhat variable in their Gram stain and display a range of cellular morphologies from coccoid, pleomorphic spherules *(Fusobacterium necrophorum)* to rod shaped. Rods can be short with rounded ends or long and thin with pointed ends *(F. nucleatum)*, arrayed end to end

Although older sources state that *Fusobacterium* is part of the normal flora of the human oropharynx, the current consensus is that *Fusobacterium* should always be treated as a pathogen.

Fusobacterium necrophorum

- Gram negative, non spore forming anaerobe, fusiform or pointed rod bacteria. Its normal inhabitant is the alimentary tract of animals and humans, the source of infection is always endogenous.
- Virulent spp. Include Fusobacterium necrophorum, Fusobacterium equinum, and Fusobacterium nucleatu

- They differ morphologically and biologically. The organism is an opportunistic pathogen that causes numerous necrotic conditions called (necrobacillosis) such as bovine hepatic abscesses, ruminant foot abscesses and human oral infections.

Pathogenesis

- The pathogenic mechanism of necrophorum is complex and not well defined. Several toxins, such as leukotoxin, endotoxin, haemolysin, haemagglutinin and adhesin, have been implicated as virulence factors. Among these, leukotoxin and endotoxin are believed to be more important than other toxins in overcoming the host's defence mechanisms to establish the infection.

Diseases

- Foot abscesses in Cattle and Sheep infection of the interdigital and adjacent soft tissues and is the major cause of lameness in beef and dairy cattle. Foot rot in sheep is a mixed bacterial infection of the interdigital skin.
- Thrush (hoof infection) horses caused by F. necrophorum.

- Bovine mastitis (summer mastitis) caused by F necrophorum alone has been reported F. necrophorum is the primary aetiological agent of bovine hepatic abscesses, from which it is frequently isolated in pure culture.
-

Diagnosis

- Gram stain reveals long gram negative fusiform rods with characteristic beading.
- Colonies are small, smooth, yellowish white, and may be α or β hemolytic.

- **Treatment :**
- Erythromycin , Tetracycline and penicillin for prevention of bovine foot rot in sheep
-

Antibiotic sensitivity and biochemical test

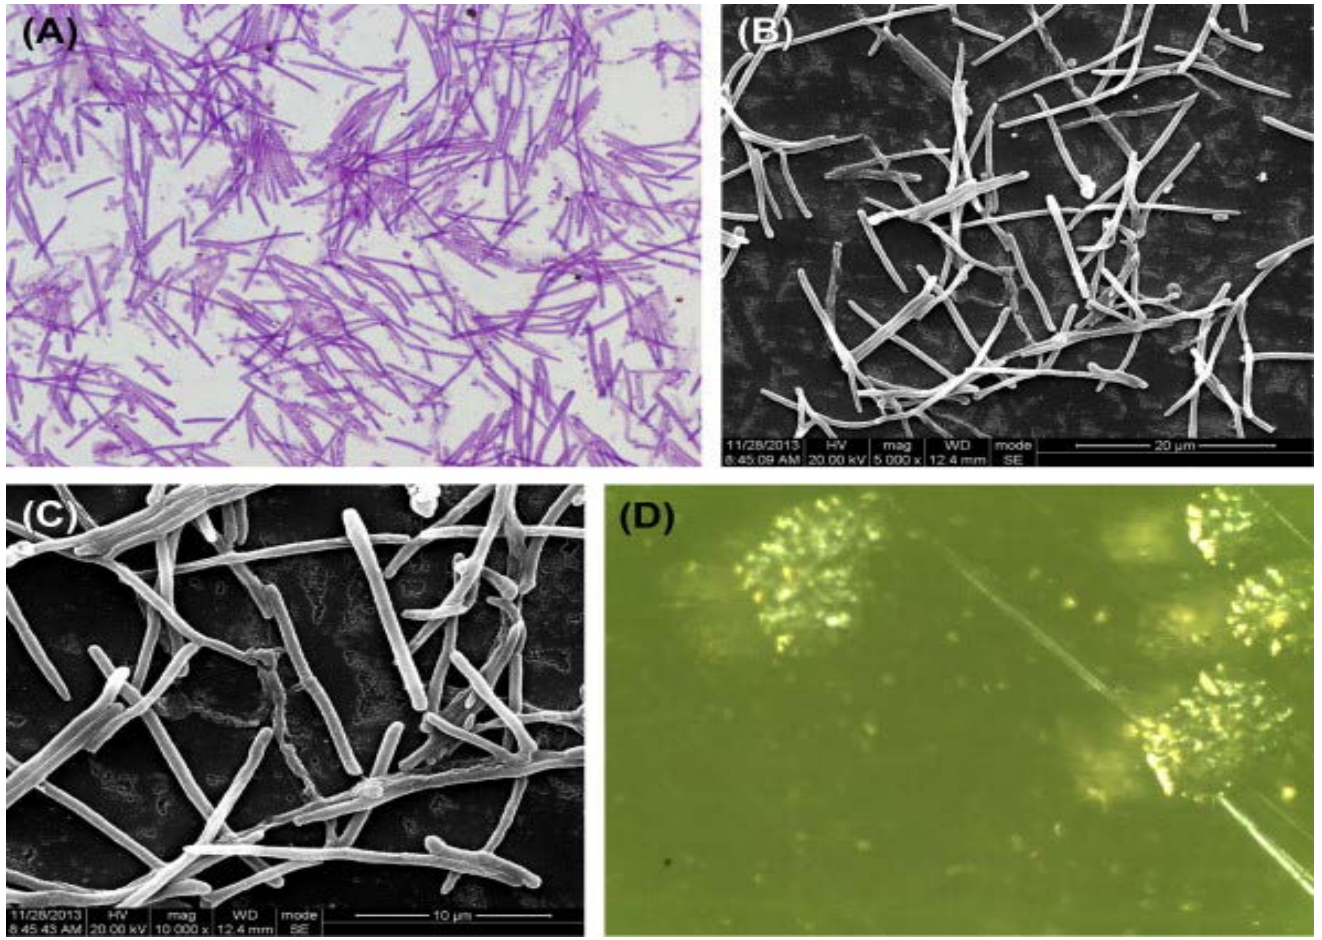
- As a genus, *Fusobacterium* is sensitive to both kanamycin and colistin and resistant to vancomycin. It can be distinguished by its bile sensitivity. Most species are indole positive and produce butyric acid during the fermentation of glucose.

Leptotrichia

Leptotrichia species are typically large, fusiform-shaped, non-sporulating, and non-motile rods, facultative anaerobic / anaerobic bacteria that are found mostly in the oral cavity and some other parts of the human body, in animals, and even in ocean sediments. All species ferment carbohydrates and produce lactic acid that may be involved with tooth decay.

-

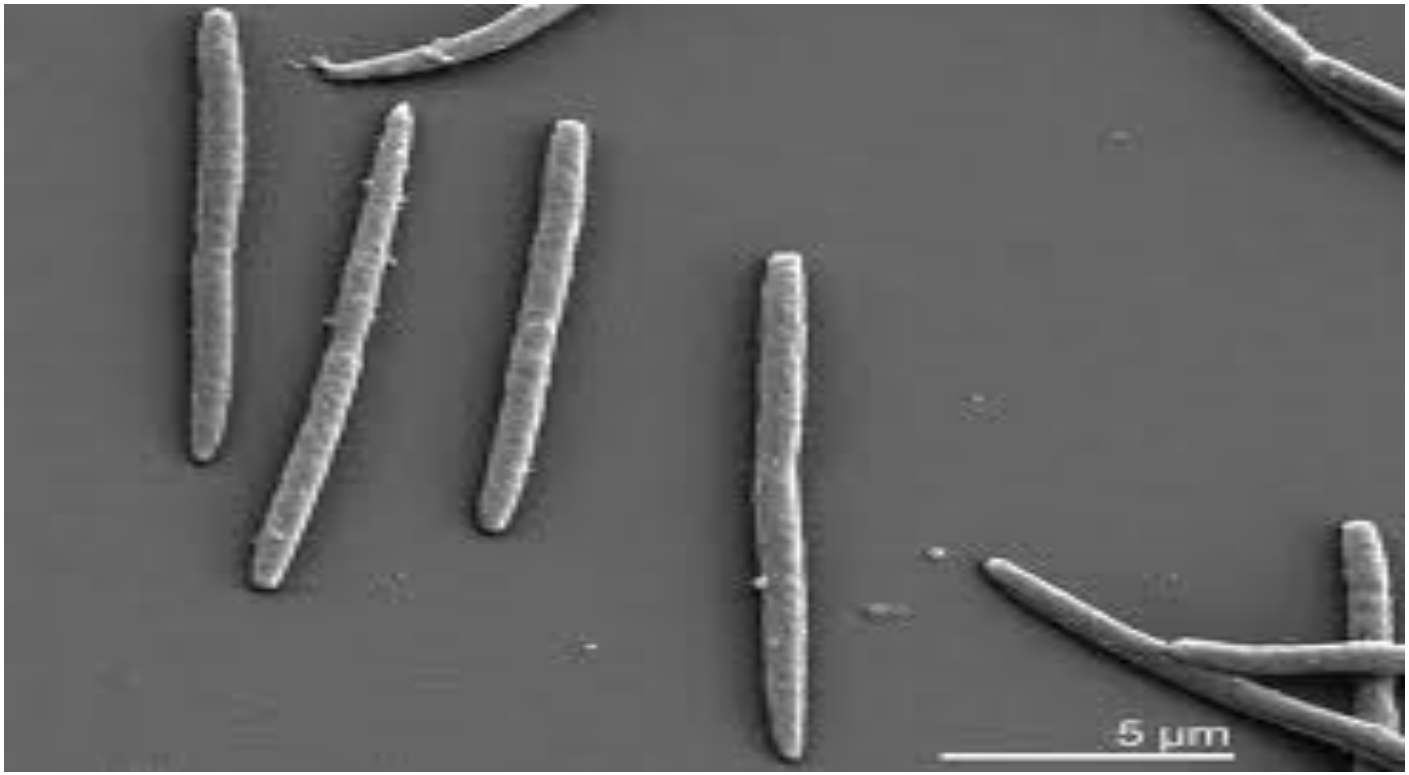
Leptotrichia Spp. (A) *Leptotrichia* cells (Gram stain). (B) *Leptotrichia* cells (SEM). (C) *Leptotrichia* cells (SEM). (D) *Leptotrichia* colonies.



Leptotrichia buccalis

- ***Leptotrichia buccalis*** is an anaerobic, Gram-negative rod bacteria. It is a constituent of normal oral flora.
- *Leptotrichia buccalis* can be clearly identified using live blood analysis in dark field. They have a distinct form, which separates them from other rod forms.

Leptotrichia buccalis



Pathology

- Almost every case of severe infection with *Leptotrichia buccalis* reported in medical literature occurred in patients with neutropenia, Holistic dentists claim that dental granulomas following root canal fillings are likely to be caused by *Leptotrichia buccalis*. The majority of patients with '*Leptotrichia buccalis* found in their blood have had root canal fillings, which would support the claim of holistic dentists.

- Thirty-one cases of bacteremia and four cases of wound infections associated with *Leptotrichia* species. Bacteremia caused by *Leptotrichia* species were found among neutropenic patients with various forms of predisposing diseases such as bone-marrow transplants, infective endocarditis, and sepsis associated with mucositis.

Identification of *Leptotrichia* species

Identification of *Leptotrichia* species can be problematic in terms of culturing because some strains are strictly anaerobic or facultative anaerobic, while others prefer growth under the influence of CO_2. *Leptotrichia* species usually stain Gram-negative, but fresh cells may be Gram-positive.

-

- It can ferment fructose, glucose, maltose, mannose, sucrose, and trehalose to produce acid. Do not produce indole, catalase, urease, H_2S and phospholipase.

Spirochaetes

Spirochaetes

- The spirochetes are a distinct group of bacteria which have :
- a unique cell morphology and mode of motility. Spirochetes are simple Gram-negative bacteria, have a characteristic long helical shape.

SPIROCHETES

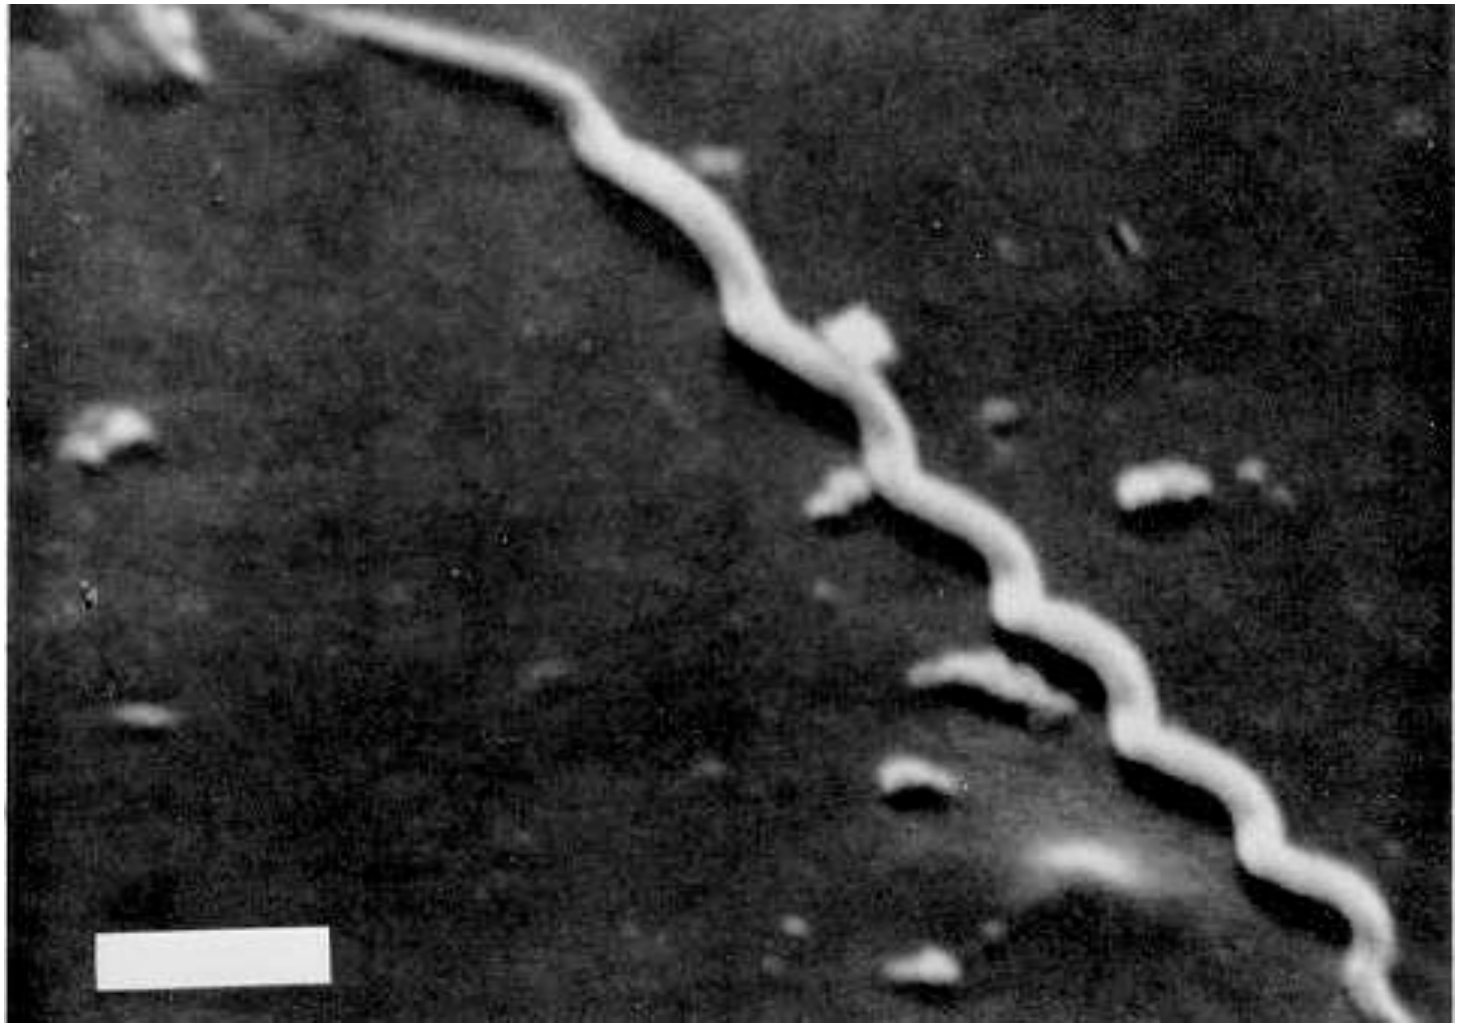
Spirochetes, a group of five genera, very widespread in nature and found in the fresh waters, of which are pathogenic for humans:

- ***Treponema***
- ***Borrelia***
- ***Leptospira***

Disease-causing members of these Genera

- *Treponema pallidum*, which causes syphilis
- *Leptospira* species, which causes leptospirosis
- *Borrelia recurrentis*, which causes relapsing fever

Treponema pallidum (Nichols strain) attached to cultured mammalian cells.

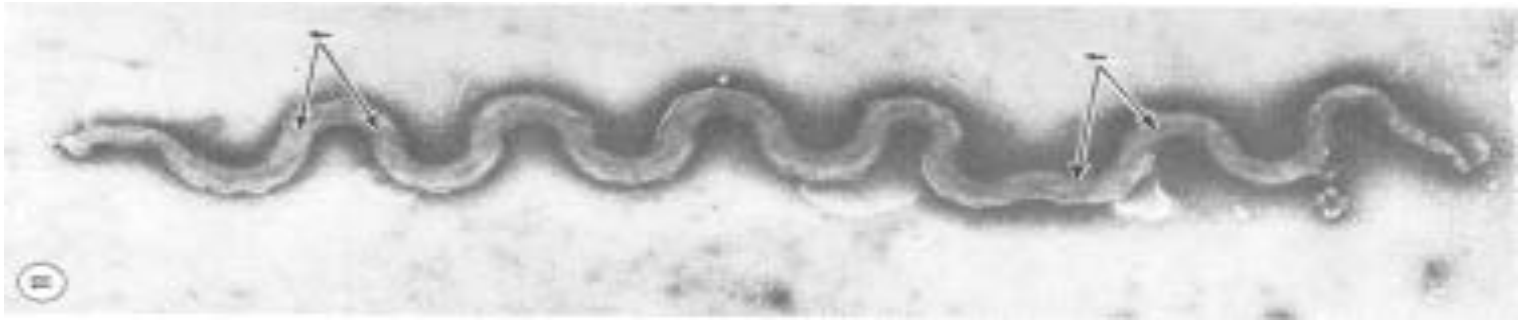


- Some are tightly coiled like a telephone cord, while others are more open;

  Very tight coils are seen in Leptospira,

  Medium coils in Treponema and

  Open coils are seen in Borrelia.

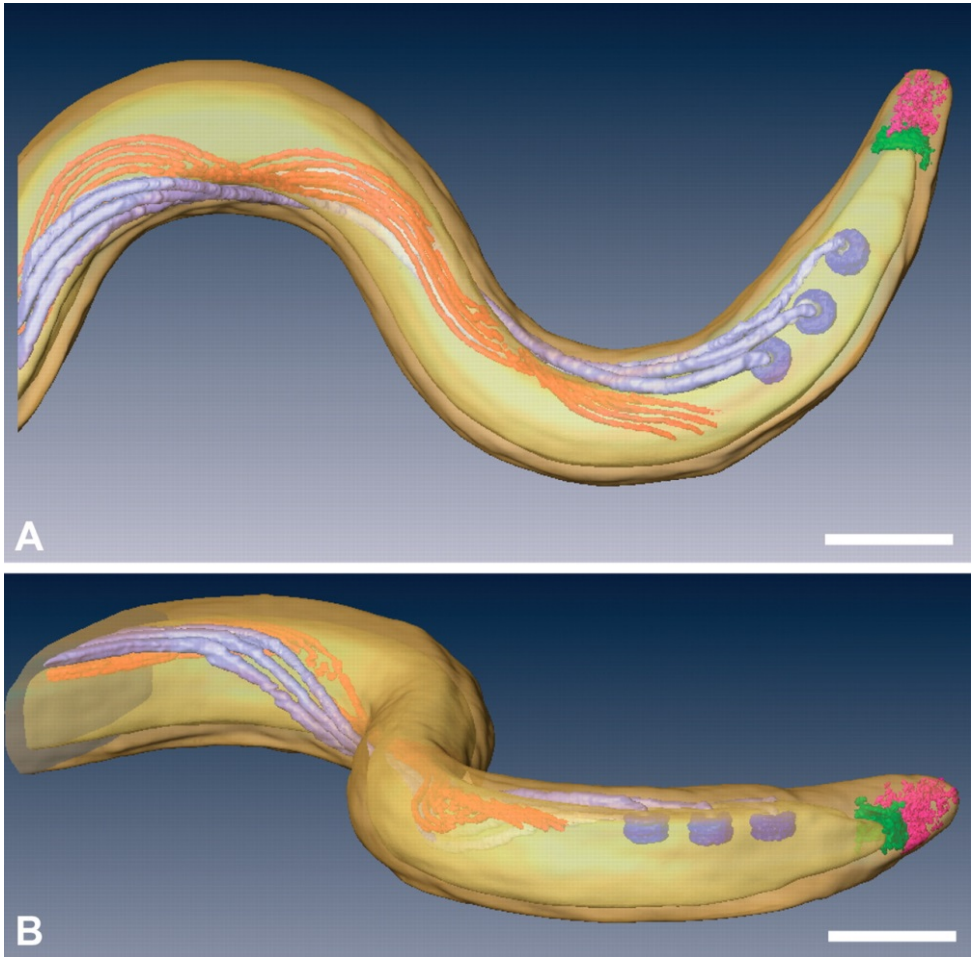


- ***Treponema pallidum***
- Exhibits characteristic motility that consists of rapid rotation about its longitudinal axis and bending, flexing, and snapping about its full length
- Multiplication is by binary transverse fission.
- Treponemes have not yet been cultured in vitro. *Treponema pallidum* is the causative agent of syphilis, a sexually transmitted disease (STD).

TREPONEMES

CELL WALL STRUCTURE

- The organism has an outer membrane containing an extremely low density of surface-exposed transmembrane proteins.
- Typically, three flagella originate from each end of the bacterium, and, winding about the bacterium within the periplasmic space, overlap at the midpoint.



Treponema

- **Virulence Factors**
- Several gene products associated with virulent strains,
  - Their roles in pathogenesis are unknown.
- The outer membrane proteins are associated with adherence to the surface of host cells,
- Virulent spirochetes produce hyaluronidase, which may facilitate perivascular infiltration.
- Virulent spirochetes are also coated with host cell fibronectin, which can protect against phagocytosis.

PATHOGENESIS

- Treponemes are highly invasive pathogens which often disseminate relatively soon after inoculation.

- Evasion of host immune responses appears to be, at least in part, due to the unique structure of the treponemal outer membrane (i.e., its extremely low content of surface-exposed proteins).

- Although treponemes lack classical lipopolysaccharide (endotoxin), they possess abundant lipoproteins which induce inflammatory processes.

Transmission of Syphilis

A. Syphilis is spread mostly by sexual contact.

B. except for congenital syphilis, which is spread from mother to fetus transplacentally or by passage through an infected birth canal.

C. Transmission by transfusion has been documented.

Chain of infection

Transmission by sexual contact requires:

1-exposure to moist lesions of skin or mucous membranes.

2- Depends on the existence of infectious lesions (sores), which may or may not be visible.

3- To disseminate away from the site of initial entry, organisms must traverse the viscous ground substance between tissue cells.

Treatment

- Syphilis is relatively easily treated with antibiotics such as penicillin, usually given as consecutive daily intramuscular injections. Patients who are allergic to penicillin may be treated with tetracycline.
- Fortunately, unlike other STDs such as gonorrhea, there is little evidence of antibiotic resistance developing in syphilis.

Thank you

Miscellaneous microorganism

a-Rickettsia and Chlamydia.

b-Mycoplasma

c-Veillonella

Chlamydiae, Rickettsiae and mycoplasmas are a miscellaneous group of organisms with properties common to both bacteria and viruses.

Chlamydiae

The chlamydiae are a group of microorganisms related to Gram-negative bacteria . However, unlike bacteria, they are unable to grow on inanimate culture media. Their main characteristics include the following

• Larger than most viruses and hence visible by light microscopy.

• Both DNA and RNA are present.

• Obligate intracellular parasites with a complex growth cycle.

• Sensitive to tetracycline, erythromycin, sulphonamides.

There are three species in the genus *Chlamydia*:

1. *Chlamydia trachomatis* is an agent of many diseases

2. *Chlamydia pneumoniae* causes acute respiratory tract infection, including sore throat, mild pneumonia and fever in humans.

3. *Chlamydia psittaci* primarily causes disease **(psittacosis)** in birds such as pet parrots and budgerigars, from which humans contract the infection. The human infection, also known as psittacosis, takes the form of a primary a typical pneumonia.

Chlamedia trachomatis : Causes a spectrum of diseases. the real number of chlamydia infections every year may be closer to 3 million.

Ocular infections - Trachoma is a chronic conjunctivitis caused by Chlamydia trachomatis. It was once the most important cause of blindness worldwide, The infection can be spread from eye to eye by fingers, shared towels or cloths, coughing and sneezing and eye-seeking flies. Symptoms include mucopurulent ocular discharge, irritation, redness, and lid swelling. Newborns can also develop chlamydia eye infection through childbirth

_ Genital infections – non-specific urethritis, the most common sexually transmitted disease in the UK . Most people who are infected have no symptoms . In the tropics, it causes lymphogranuloma venereum

Chlamydia is caused by a bacterial infection. The only true cure for this type of infection is antibiotics.

But some alternative treatments may help ease symptoms, untreated chlamydia can lead to long-term complications, including fertility problems and chronic inflammation.

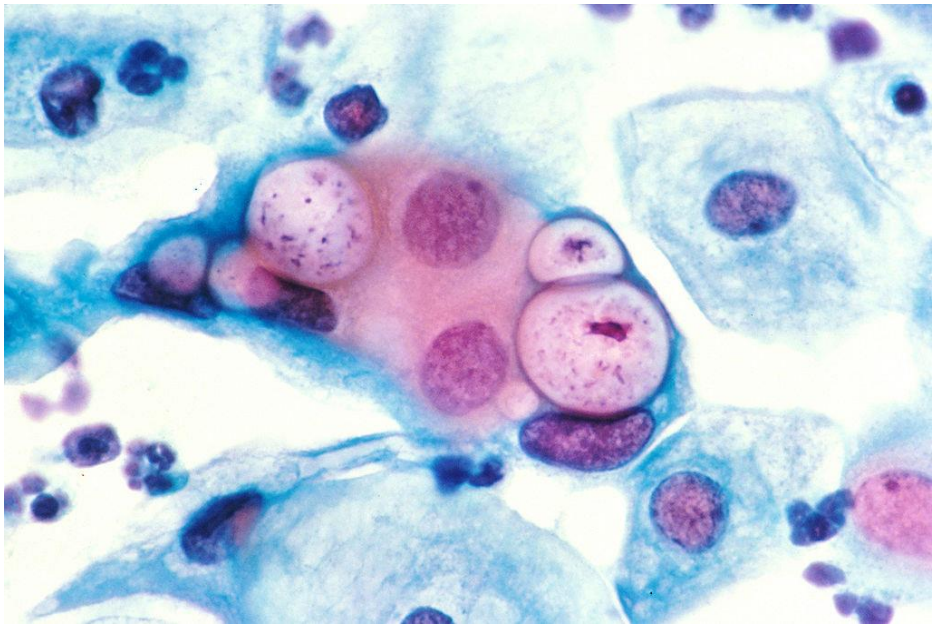


Fig 1:-Pap Smear Description: Human pap smear showing chlamydia in the vacuoles at 500x and stained with H&E.

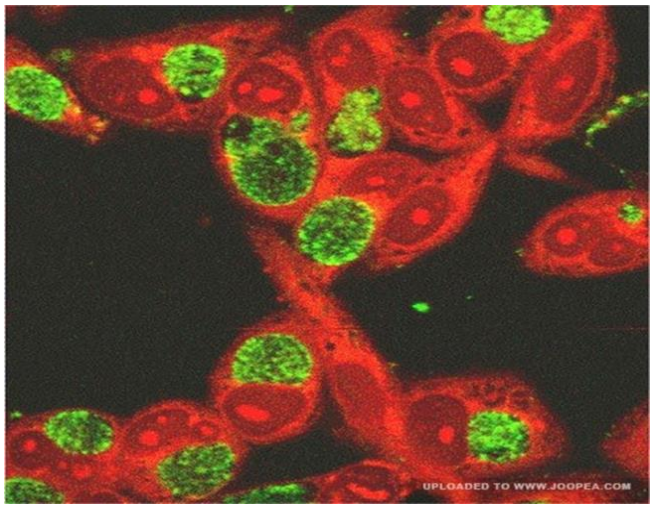
Pneumonia – in neonates. Newborn babies can acquire chlamydia from their mother during .birth

Culture and diagnosis

Identified by tissue culture (e.g.Hela cells) ,serology (complement fixation tests)and fluorescent antibody staining of smears from the lesion.



Hela cells :-is an immortal cell line used in scientific research. It is the oldest and most commonly used human cell line. The line is derived from cervical cancer cells taken on 1951, from Henrietta Lacks, a 31-year-old African-American, who died of cancer. The cell line was found to be remarkably durable and prolific, which allows it to be used extensively in scientific study

Antibiotic sensitivity

Tetracycline is effective for all chlamydial infections.

Rickettsiae

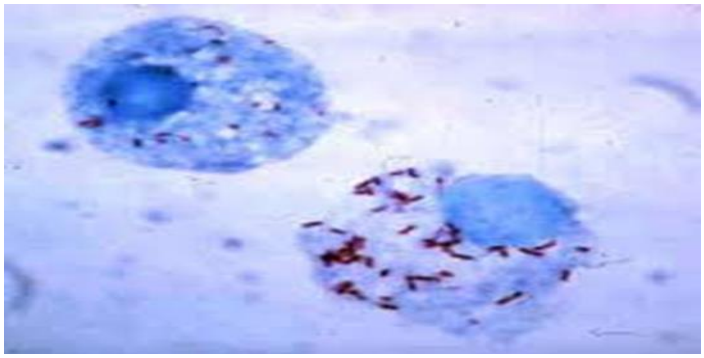
Rickettsiae are pleomorphic organisms, smaller than bacteria but resembling them structurally and metabolically, including cell wall formation. They, like Chlamydia and viruses. The best-known human rickettsial disease is typhus, which spreads wildly in conditions of malnutrition _Coccobacilli, with a multilayered outer cell wall resembling that and poverty. Rickettsiae are of Gram-negative bacteria cell wall. Rickettsias are generally sensitive to environmental exposure, although R. typhi can survive several years in dried flea droppings

_Obligate intracellular parasites that replicate by binary fission .

_Visible by light microscope when special stains are used(e.g.Giemsa).

_Able to infect many species, including arthropods, birds and mammals; members of the genus are transmitted to humans via bites of infected arthropods

Sensitive to tetracycline and chloramphenicol.



_

Distribution and Ecology of Rickettsial Diseases

The Role of Arthropod Vectors

The rickettsial life cycle depends upon a complex exchange between blood-sucking arthropod hosts and vertebrate hosts. Eight tick genera, two fleas, and one louse are involved in the spread of rickettsias to humans.

General Factors in Rickettsial

Pathology and Isolation

A common target in rickettsial infections is the endothelial lining of the small blood vessels. The bacteria recognize, enter, and multiply within endothelial cells, causing necrosis of the vascular lining

Among the immediate pathologic consequences are vasculitis, perivascular infiltration by infl ammatory cells, vascular leakage, and thrombosis. These pathologic effects are manifested by skin rash edema, hypotension, and gangrene. Intravascular clotting in the brain accounts for the stuporous mental changes and other neurological symptoms that sometimes occur

There are two genera within the Rickettsieae:

Rickettsia and Coxiella.

Rickettsia

Rickettsial diseases include:

Epidemiology of Epidemic Typhus Humans are the sole hosts of human body lice and the only reservoirs of *R. prowazekii.* The louse spreads infection by defecating into its bite wound or other breaks in the skin. Infection of the eye or respiratory tract can take place by direct contact or inhalation of dust containing dried louse feces, but this is a rarer mode of transmission.

TABLE 21.2 Characteristics of Major Rickettsias Involved in Human Disease

Disease Group	Species	Disease	Vector	Primary Reservoir	Mode of Transmission to Humans	Where Found
Typhus	*Rickettsia prowazekii*	Epidemic typhus	Body louse	Humans	Louse feces rubbed into bite; inhalation	Worldwide
	R. typhi (mooseri)	Murine typhus	Flea	Rodents	Flea feces rubbed into skin; inhalation	Worldwide
Spotted Fever	*R. rickettsii*	Rocky Mountain spotted fever	Tick	Small mammals	Tick bite; aerosols	North and South America
	R. akari	Rickettsialpox	Mite	Mice	Mite bite	Worldwide
Scrub Typhus	*Orientia tsutsugamushi*	—	Immature mite	Rodents	Bite	Asia, Australia, Pacific Islands
Human Ehrlichiosis	*Ehrlichia chaffeensis*	Human monocytic ehrlichiosis	Tick	—	Tick bite	Similar to Rocky Mountain spotted fever
Human anaplasmosis	*Anaplasma phagocytophilum*	Human granulocytic anaplasmosis	Tick	Deer, rodents	Tick bite	Unknown

:Rocky Mountain Spotted Fever

Epidemiology and Pathology

The rickettsial disease with greatest impact on people living in North America is Rocky Mountain spotted fever ,etiologic agent *Rickettsia rickettsii* in smears from infected animals and patients and later discovered that it was transmitted by ticks.

Pathogenesis and Clinical Manifestations of Spotted Fever

After 2 to 4 days incubation, the first symptoms are sustained fever, chills, headache, and muscular pain. Early diagnosis can be made by staining rickettsias directly in a tissue biopsy using fluorescent antibodies. Isolating rickettsias from the patient's blood or tissues is desirable, butit is expensive and requires specially qualified personnel and laboratory facilities. Specimens taken from the rash lesions are suitable for PCR assay, which is very specific and sensitive and can circumvent the need for culture.

Coxiella

Coxiella burnetii, an organism closely resembling rickettsiae,. Rickettsial diseases include:
Typhus, (typhus fever)
Typhus group of infectious diseases that include epidemic typhus, scrub typhus, and murine

typhus. Common symptoms include fever, headache, and a rash.
Typically these begin one to two weeks after exposure Usually Q fever presents as a 'non-bacterial' pneumonia, but lesions may be seen in the brain and other organs, including the heart, with resultant infective endocarditis.

Culture and diagnosis

Isolation of most rickettsias from clinical specimens requires a suitable live medium and specialized laboratory facilities, including controlled access and safety cabinets. The usual choices for routine growth and maintenance are the yolk sacs of embryonated chicken eggs, chick embryo cell cultures, and, to a lesser extent mice and guinea pigs.• Serology: rising titer of antibody in patients sera.

Antibiotic sensitivity: Tetracycline or chloramphenicol.

Mycoplasmas

Mycoplasmas are the smallest prokaryotes capable of binary fission, and they grow, albeit slowly, on inanimate media. Mycoplasmas are indeed wall-less bacteria, without the peptidoglycan cell wall but bound by a plasma membrane consisting of lipids and sterols (including cholesterol). Hence, they are highly pleomorphic. Analysis of *Mycoplasma* genome sequences (16SrDNA) suggests that these organisms are most closely related to *Bacillus–Lactobacillus* and *Streptococcus* sub groups of Gram positive bacteria. The most important species of the genus *Mycoplasma* is *Mycoplasma pneumoniae*, which causes**:**

_A common pneumonia, atypical pneumonia

_ Mucocutaneous eruptions, including the oral mucosa

_ Haemolytic anaemia.

Mycoplasma pneumoniae

Primary atypical pneumonia

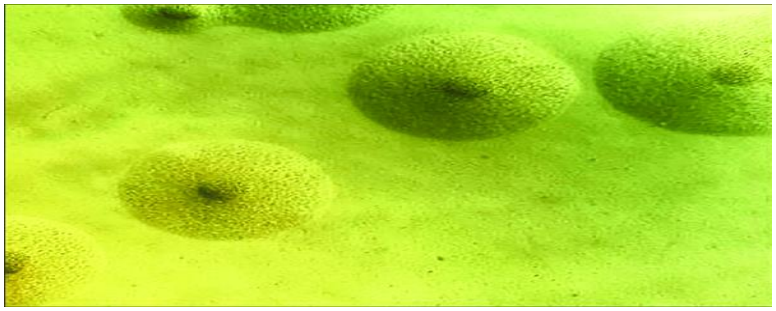
Primary atypical pneumonia takes the form of fever, non productive cough, severe headache, weakness and tiredness. The acute illness lasts for about 2 weeks, but in a majority, the symptoms last longer.

Mucocutaneous eruptions

M. pneumoniae may cause skin rashes and ulcerations of both the oral and vaginal mucosa.. The skin lesions, which often affect the extremities, have a target or iris appearance(**target lesions**). In the oral mucosa, erythematous patches may appear first, quickly becoming bullous and erosive. This leads to extensive blood encrustations, especially the labial lesions. When the oral ulceration is associated with the skin rash and conjunctivitis, it is called **Stevens–Johnson syndrome**.

Culture and diagnosis

Mycoplasma can be cultured in special media but is a slow grower (about 10 days); the colonies have a characteristic fried-egg' appearance. Immunofluorescence of colonies transferred to glass slides is useful (as they do not take up the Gram stain well).Serology is useful as the culture results are delayed. Complement fixation testing for *M. pneumoniae* antibodies is diagnostic.



Antibiotic sensitivity: Tetracycline for adults and erythromycin for children.

Oral mycoplasmas

Mycoplasmas have been isolated from saliva, oral mucosa and dental plaque, but their significance is not clear. The oral species are poorly characterized and include *Mycoplasma buccale*, *Mycoplasma orale* and *Mycoplasma salivarium*. The latter two species have been isolated from salivary glands and are thought to play a role in salivary gland hypo function. Estimates of the oral carriage of mycoplasma vary from 6% to 32%.

Veillonella

Veillonella spp. are non-motile, gram-negative diplococci ,anaerobic .

Veillonella is part of the normal flora of the mouth and gastrointestinal tract and may be found in the vagina. *Veillonella* species are common and considered mainly harmless, or even beneficial, colonizers of the mouth from the early years of life onward .V. parvula subsp. parvula is detected in saliva, on the tongue, and in plaques. They are able to utilize lactate produced by *Streptococcus mutans*, and are thus considered as beneficial bacteria in dental .plaques.

Veillonella spp. are often regarded as contaminants; they are often associated with oral infections; bite wounds; head, neck, and various soft tissue infections; and they have also been implicated as pathogens in infections of the sinuses, lungs, heart, bone, and CNS. Recent reports have also indicated their isolation in pure culture in septic arthritis and meningitis**.**
